perception of brand equity

Randle D. Raggio

WHAT BRAND EQUITY IS

Derived from the concept that a brand represents a promise of salient benefits to a set of target consumers (Blackett, 2003), *brand equity* is the perception that a brand delivers on its promise of benefits (Raggio and Leone, 2007). This definition implies that brand equity is an intraindividual concept—that is, it lives in the hearts and minds of consumers. It is also context specific, in that a person can hold a high amount of brand equity for a brand on particular occasions, but not on other occasions, as the salience and importance of the promise, and the brand's ability to deliver on that promise, can be perceived to change across occasions (e.g., Lava soap may enjoy high brand equity among do-it-yourself auto mechanics in the shop, but this equity may not transfer to more common domestic cleaning situations) (Raggio and Leone, 2007).

WHAT BRAND EQUITY DOES

Brand equity moderates the impact of brand-related information such as advertising, product-use experience, and word of mouth, producing more favorable customer reactions toward a product and the way it is marketed when the brand is identified, as compared to when it is not (Keller, 2008). Those who hold high amounts of brand equity are more likely to believe positive information about the brand, less likely to believe, or more likely to discount or counterargue, negative information, and more likely to give the brand the benefit of the doubt (e.g., when faced with product quality problems, product harm crises, or price or product challenges from competitive brands, etc.).

OUTCOMES OF BRAND EQUITY

Potential outcomes of brand equity include positive brand image, higher perceived quality, brand-name awareness, brand loyalty, brand choice, higher willingness to pay a price premium, more favorable reaction to brand extensions, less vulnerability to competitive

marketing tactics, and so on (Keller, 2008), and it may produce these effects in consumers, channel partners, potential employees, government/regulatory agencies, financial institutions, and so on (Raggio and Leone, 2007). As a result, brand equity is a valuable intangible asset for a firm, through its ability to positively impact the cash flow of the firm that owns it or uses it, for example, through licensing agreements (*see* BRAND VALUE for more information on how brand equity impacts brand value). However, related to the idiosyncratic nature of brand equity described above, some consumers may hold high levels of brand equity but not (yet) be prospective users of the brand, so the lack of specific marketplace behaviors by a particular set of consumers (e.g., purchase) is not evidence that brand equity does not exist (e.g., luxury goods, baby-care products, college education, etc.) (Raggio and Leone, 2007). Likewise, because brand equity is based on consumer perceptions, specific marketplace behavior (e.g., purchase—even at a price premium) is not necessarily an indication that brand equity does exist, as some purchases may be driven by product attributes or ingredients, price, induced behavioral loyalty (e.g., airline frequent-flyer membership), or availability (Raggio and Leone, 2007).

BRAND EQUITY AS AN ASSET

Though brand equity is a valuable intangible asset, it is not a separable asset that can be traded in the marketplace like a patent, trademark, logo, or certain brand associations (e.g., paid endorsements) (Barwise, 2003), or valued accurately apart from the specific firm that owns or uses the brand, or a context-specific usage or consumer behavior. For example, it may be possible to determine the impact of brand equity on favorable impressions of a brand extension, but the effect may be different if the extension were produced by a license, or if the focal outcome were changed to willingness to pay a price premium. Measures of brand equity should consider both its immediate effects on current prospects and its ability to attract new users who are not currently prospects for what the brand has to offer (Raggio and Leone, 2007).

BUILDING BRAND EQUITY

Brand equity is built by what the brand *has* and what the brand *does* to create the perception that the brand indeed meets its promise of benefits. Strong, positive, and unique brand associations are necessary to build brand equity, and can be driven by the product itself through salient attributes/features/ingredients and through its performance, linkages to positive feelings, memories, images, judgments, and so on, or by other proprietary brand assets such as patents, trademarks, exclusive distribution contracts, or endorsements that competitors cannot copy, to create a brand that resonates with consumers in context-specific usage (Keller, 2008).

customer equity

Katherine N. Lemon and Loren J. Lemon

Customer equity is defined as the total lifetime value of a firm's current and potential customer base. The customer equity (CE) construct can be utilized via both a conceptual framework (CE framework) and a mathematical model (CE model) which will allow a firm to evaluate various marketing initiatives, either conceptually or by a potential-ROI analysis, in order to create, manage, and grow the firm's CE (Blattberg and Deighton, 1996; Rust, Lemon, and Zeithaml, 2004; Rust, Zeithaml, and Lemon, 2000). The CE framework utilizes three primary elements that drive the creation and dynamic growth of CE: value, brand, and relationship.

The "value driver" is the customer's assessment of the utility of the firm's offering based on the customer's objective perception of what is given up for what is received. Typical subcomponents are *quality*, *price*, and *convenience*. *Quality* encompasses the customer's objective perception of the physical and nonphysical attributes of the offering. *Price* represents "what is given up by the customer," usually, but not always, money. *Convenience* relates to the customer's time and other costs in obtaining the offering and doing business with the firm (see SERVICES MARKETING STRATEGY; A FRAMEWORK FOR CREATING VALUE PROPOSITIONS).

The "brand driver" is the customer's subjective/intangible assessment of the firm and the offering. Typical subcomponents are *brand awareness*, *brand perceptions*, and *firm ethics*. *Brand awareness* encompasses those firm actions (e.g., advertising) that influence and enhance the customer's awareness of the subject brand. *Brand perceptions* deals with the customer's attitude toward that brand (i.e., how much the customer identifies with, or subjectively values, the brand). *Firm ethics* deals with the firm's acts or omissions that influence the customer's subjective perceptions of the firm (e.g., charitable/community activities, privacy policies, and corporate misconduct) (see PERCEPTION OF BRAND EQUITY; BRAND VALUE; BRAND GROWTH STRATEGY; BRAND STRATEGY).

The "relationship driver" is the customer's tendency to stick with a firm for reasons other than just the customer's objective and subjective assessments of the firm's offerings or brand, and focuses on the direct (or indirect) interactions between the customer and the firm. Typical subcomponents are *loyalty programs*, *affinity programs*, and *community-building programs*. *Loyalty programs* reward the customer for specific behaviors (e.g., flying on the airline) with tangible benefits (e.g., free tickets). *Affinity programs* seek to create strong emotional ties with the customer by connecting the firm's offering with other aspects of the customer's life (e.g., college alumni Visa cards). *Community-building programs* link a customer with a group of other like customers of the firm (e.g., Harley Owner Groups (HOGS)) (see SERVICES MARKETING STRATEGY).

Implementation of the CE framework begins with the determination regarding which of the drivers are key for the target customers. (This can be determined by a variety of ways; usually target customers are surveyed to determine their perceptions of the company's and its competitors' performance with regard to the CE drivers) (see CUSTOMER ANALYSIS). The firm then assesses its performance on the identified key drivers, and compares its performance with the relative importance of such drivers to the customer and relative to its competitors.

Using additional data necessary to calculate individual average CUSTOMER LIFETIME VALUE (CLV) and the aggregate firm CE, the firm can utilize the CE model to determine the potential relative impact that various marketing initiatives may have on the firm's CE. (While the detailed mathematics behind the model are beyond the scope of this article, the model takes into account brand switching patterns, Markov chain analysis, demographic projections, life expectancy forecasts, and value discounting) (see CUSTOMER RELATIONSHIP MANAGEMENT). By running the CE model on a variety of potential marketing initiatives, the firm can then compare and rank the various initiatives on a "CE return on marketing investment" perspective.

With insights derived from the CE framework and CE model, a firm can tailor its marketing

2 customer equity

efforts to meet unfulfilled customer expectations, and identify and exploit situations in which the firm has a competitive advantage vis-à-vis its competitors (*see* MARKETING STRATEGY MODELS; A FRAMEWORK FOR CREATING VALUE PROPOSITIONS). This allows the firm to make a more disciplined and informed decision on which marketing initiatives to implement and at what levels.

brand growth strategy

Victoria L. Crittenden

INTRODUCTION

The strategic opportunity matrix identifies four major strategic alternatives for company growth: market penetration, market development, product development, and diversification (Ansoff, 1957). Brands are fundamental components of each of these strategic growth options, and the company's **MARKETING STRATEGY** depends strongly on decisions surrounding brand strategies (see **BRAND STRATEGY**) within the larger context of **MARKETING PLANNING**.

Evolving over time, brand strategies range from corporate brands to individual brands. This evolution is driven by competitor innovations, changes in customers' wants and needs, and overall neglect that leads to atrophy of brand value (Capon *et al.*, 2001). The potential harm to **BRAND VALUE**, brand equity (see **PERCEPTION OF BRAND EQUITY**), and **CUSTOMER EQUITY** has long-term ramifications for shareholder value. Both business-to-consumer and business-to-business companies should plan strategically with respect to brand architecture. That is, all companies must understand the various strategies for brand growth so as to create brand value/equity and customer equity which lead to long-term shareholder value.

Brand growth strategies. The five major strategies for brand growth are line extension strategy, brand extension strategy, cobranding strategy, flanker strategy, and new brand strategy. There are no hard and fast rules as to when one brand growth strategy takes precedence over another. Brand growth requires a unique blend of art and science. Careful monitoring of the marketplace with respect to competition and customer desires is critical to brand growth strategy formulation.

Line extension strategy. The line extension strategy, probably the most common brand growth strategy, is a powerful tool in a product manager's toolbox. A line extension is when a parent brand is used to brand a new product that targets a new market segment within the product category served currently by the parent brand (Keller, 2007). A fairly common example

of the line extension strategy is Crest toothpaste. A quick scan of the Procter and Gamble website highlights the depth of line extensions. For example, Crest toothpaste comes in a wide variety of product offerings: Pro Health, Weekly Clean, Whitening Expressions, Whitening, Cavity Protection, Tartar Protection, Sensitive Teeth, Flavors, Baking Soda, Gels, Liquid Gels, Paste, Striped, and For Kids.

In the Crest example, the relationship between the core brand (Crest) and the line extensions is that Crest serves as the endorser of the extensions. A consumer may purchase whitening toothpaste for the benefits of whitening, but purchase Crest Whitening for the assurance of the Crest brand. Yet, Whitening would likely carry no weight as a stand-alone brand without the endorsement of Crest. In other instances of line extension, both the core brand and line extension exert influence on consumer decision making. The Toyota Avalon, Toyota Camry, and Toyota Corolla are examples of line extensions where the core brand (Toyota) and the extensions (Avalon, Camry, and Corolla) are important designators of brand building power.

Product managers must keep in mind the line logic when considering line extensions. Line LogicTM is a disciplined approach to creating and presenting a full complement of product line extensions (Reffue and Crittenden, 2006). The six interrelated elements in the Line LogicTM framework are segmentation, naming conventions, design elements, tiered feature sets, pricing, and packaging. In considering the logic behind line extensions, this framework is useful for building a strong portfolio of line extensions – all of which work to complement each other and increase the overall market share and profitability. Line extensions should be a source of new revenue for a company; yet, one of the biggest fears is that the line extension will fail and damage the core brand in its failure.

Brand extension strategy. While a line extension uses the core brand name in the same product category as the original core brand, a brand extension strategy uses the brand name asset to penetrate new product categories with a new product (Aaker, 1990). The brand extension strategy utilizes brand name recognition as a way to have immediate name recognition in

2 brand growth strategy

a particular product category. Seven types of brand extensions have been suggested (Tauber, 1988). These seven types and examples of each are as follows:

1. Same product in a different form – this is one of the simplest forms of brand extension; an example of this form is when Ocean Spray created cranberry juice cocktail (a drink) by using its original food product (cranberries).
2. Distinctive taste/ingredient/component in new item – this is when a company takes a key ingredient or component of a branded product and uses that component in another product; an example is Arm & Hammer (original product was baking soda) with its Carpet Deodorizer.
3. Companion products – this is the extension of the brand into a product that can be used with the original branded product, such as Log Cabin syrup offering Log Cabin pancake mix.
4. Same customer franchise – an attempt to leverage a brand name by selling something additional to the current customer base; an example would be the American Express gift card, which is a typical gift card but leverages the American Express brand and reputation.
5. Expertise – this is when a brand extension is offered in a product category for which the customer expects the company to have expertise; for example, BIC was the leader in disposable plastic pens and transferred this disposability expertise to disposable lighters and razors.
6. Benefit/attribute/feature owned – this is when consumers tend to associate a particular attribute with a brand; an example of this is when Ivory soap used its mildness attribute to extend into a mildness positioning for shampoo for daily use.
7. Designer image status – this is when the status of the original brand extends its status to other product categories, such as the Porsche name appearing on sunglasses.

A brand extension strategy can help combat entry barriers put in place by prominent brand name domination of particular product categories. Consistent with this, the primary benefits

to the brand extension strategy are capitalization on the company's most valuable asset – its brand names, investment outlays typically necessary to establish a new brand are minimal, introduction of the new brand can increase sales for the parent brand, and reduced risk of failure (Tauber, 1988).

Yet, there can be a dark side to brand extensions. Failures are attributed to a variety of reasons (Aaker and Keller, 1990; Capon *et al.*, 2001). For example, a lack of association between old and new products can lead to consumer confusion or even consumer disinterest. Often-times, the unique image of the original brand is not transferable to the brand extension. Even worse, the extension might be perceived to be of lower quality than the original product with the same brand name. Competitively, there might already be a dominant brand in the new product category, which could lead to unexpected and/or time-consuming competitive battles.

Cobranding strategy. The cobranding growth strategy is the formation of an alliance between popular brands. While not necessarily new to the marketplace, this cobranding growth strategy has become more prevalent given the popularity of alliances as a growth strategy in general. The synergy created by two well-matched brands can clearly enhance long-term value to the firm, with products signaling unobservable qualities by having a brand ally (Blackett and Boad, 1999; Rao, Qu, and Ruekert, 1999).

A physical cobranding growth strategy occurs when the two brands come together to form one product. Examples include a Dell PC with Intel inside and Diet Coke with NutraSweet. Ford Motor Company, however, has tried its hand at a different form of a cobranding growth strategy. In the mid-2000s, the company introduced the Ford F-150 Harley-Davidson. In the early 1990s, Ford cobranded with Eddie Bauer to offer Eddie Bauer branded Ford vehicles. Both of these Ford examples represent a cobranding that is more symbolic in nature in that neither Harley-Davidson nor Eddie Bauer provided component parts to the vehicles. Instead, the cobranding strategies at Ford were meant to relate Ford and Harley-Davidson/Eddie Bauer in the minds of the consumers and

signal an unobservable aspect of the Ford vehicles.

Following a cobranding growth strategy has many benefits, not the least of which is bringing together the power of two strong brands to the marketplace thus enabling a new product to tap into the market following of both brands. On the flip side, however, companies must be careful when bringing together disparate brands that might cause confusion in the consumer's mind. For example, some consumers might not opt for the Eddie Bauer version of the Ford if they are unsure as to the significance of an Eddie Bauer vehicle, instead attributing Eddie Bauer to a line of clothing or retail stores. Additionally, neither company has control over the actions of the cobranding partner. Thus, something that harms the reputation of one could spill over and have a negative impact on the cobranded product.

Flanker strategy. The flanking strategy has its roots in warfare. As related to marketing, the flanking growth strategy is one of the MARKETING WARFARE STRATEGIES. The general idea is that a company positions products in such a way as to have a presence in various market segments. In military jargon, the flanking growth strategy reduces the maneuverability of the enemy (competitor), with a defensive flanking strategy referred to as a *flanking position* and the offensive strategy referred to as a *flanking attack*. As a defensive move, a company following a flanking growth strategy will offer products in peripheral/secondary markets so as to prevent competitive attacks on a weak or no brand position. Offensively, the flanking growth strategy is engaged to avoid a head-on or direct confrontation with an established competitor.

The flanking brand growth strategy suggests that the brand is a fighting brand. A company following this strategy generally does not want to use its leading brand in battle, as the risks are too great. Thus, the company brings out the fighting brand to battle on possibly less strategic fronts and/or to prevent the competition from gaining market entry from a vulnerable position.

Cytosport, the parent company of Muscle Milk, understands the flanking brand growth strategy. With Muscle Milk as a market leader in a growing health and nutrition marketplace,

Cytosport recognized that other companies would want a piece of this rapidly expanding marketplace. Rather than only attempting to capture this growth via line or brand extensions, Cytosport focused on Cytomax as its flanking brand. Cytomax was intended to head off attacks in expanding market segments. The company's strategy has been to offer a core brand and then have strategically derived flanking brands in market segments as necessary.

Pharmaceutical companies have also begun using flanking strategies by aligning with generic competitors in an effort to capture a share of the generic marketplace. Use of the flanking strategy in this context means that large pharmaceutical companies are not fighting head to head with the generic firms; rather the large pharmaceutical companies are using a form of cobranding as a flanking brand strategy.

A major risk in the flanker brand growth strategy is that the market segments may not be as clearly delineated as hoped. That is, consumers might trade down to the flanker brand. Thus, this is a particularly risky brand growth strategy in difficult economic times.

New brand strategy. The new brand growth strategy leverages the existing brand's marketing clout in the introduction of a completely new brand. The company may be attempting to tap into new markets that might not fit the profile of the current customer base. Thus, there is a new brand offering in a product or market class that was not served previously by the company.

Toyota has followed the new brand growth strategy quite successfully with its Lexus and Scion product offerings. Toyota introduced the Lexus to compete in the very high end of the market – a consumer market that might have been turned off by a Toyota product which is considered more for the middle, mainstream marketplace. Similarly, in the mid-2000s, Toyota sought to capture the younger demographic with the Scion. While the Lexus consumer did not see the Toyota as an upscale automobile, the younger marketplace had a difficult time seeing Toyota as a trendy and fun car to drive. Thus, Toyota entered this market with the Scion. While both Lexus and Scion consumers know that Toyota is the

4 brand growth strategy

parent company, neither group of consumers see themselves as driving a Toyota automobile. Yet, both groups know that their vehicles are backed by Toyota quality even without the Toyota brand name on the product.

In a similar move, Pepsi expanded into the non-cola market with a tea beverage named Tava. A fruit-flavored, caffeine-free drink, Tava allowed Pepsi to enter a new market with a new product. Branding the product as a Pepsi product would have enforced a strong association with a cola drink – something Tava is not. Additionally, the entirely new brand allowed Pepsi to experiment with some non-traditional media alternatives without risking Pepsi’s traditional branded products.

The Toyota and Pepsi examples portray new brand strategies that work for companies. In both instances, the companies were extending into comparable product categories in seeking new consumers. An example of a new brand strategy that did not work well was the effort by Anheuser-Busch to break into the salty snack market with Eagle Snacks. While eating salty snacks might increase beer consumption, a beer

company offering a new brand of salty snacks did not resonate with consumers.

The new brand strategy enables a company to grow without compromising its reputation in already-strong markets. A company is able to exert influence in the marketplace with its marketing clout, but it is not putting its reputation at risk. Yet, since there is no guarantee that consumers will naturally connect the goodness of the core brand with the new brand, the company is also foregoing any possible positive spillover effect.

Timing of brand growth strategies. Prominent in marketing strategy is the idea of the first mover advantage (*see* FIRST-MOVER (PIONEER) ADVANTAGE), yet brand growth strategies do not necessarily follow this early or first entry idea. For example, one study found that brand extensions entering early in the market lifecycle were more likely to fail (Sullivan, 1992). Entering late in the market lifecycle was suggested as the preferred strategy for a brand extension. Within the same study, it was found that the new brand growth strategy was likely more effective in the early stages of the market lifecycle, with early

Table 1 Summary of brand growth strategies.

| <i>Strategy</i> | <i>Core Brand</i> | <i>Growth</i> |
|-----------------|---------------------|--|
| Line extension | Crest (toothpaste) | Pro health, weekly clean, whitening expressions, whitening, cavity protection, tartar protection, sensitive teeth, flavors, baking soda, gels, liquid gels, paste, striped, for kids |
| Brand extension | Toyoto (cars) | Avalon, Camry, Corolla |
| | Ocean spray | Same product different form |
| | Arm & Hammer | Key component in new item |
| | Log Cabin | Companion product |
| | American Express | Same customer franchise |
| | BIC | Expertise |
| Cobranding | Ivory | Benefit/attribute |
| | Porsche | Designer image status |
| | Dell PC | Intel |
| | Diet Coke | NutraSweet |
| Flanker | Ford Motor Co. | Harley-Davidson/Eddie Bauer |
| | Muscle milk | Cytomax |
| New brand | Pharmaceutical Cos. | Generic manufacturers |
| | Toyota | Lexus &and Scion |
| | Pepsi | Tava |

Table 2 Disadvantages of brand growth strategies.

| Strategy | Disadvantages |
|-----------------|---|
| Line extension | Damage to core brand; cannibalization; loss of product/brand focus; dilution of brand image; brand confusion; limited shelf space |
| Brand extension | Consumer confusion; consumer disinterest; lack of transferability; unequal quality; competitive battles; potential damage to core; intrafirm competition; cannibalization |
| Cobranding | Disparate, not complementary, brands; negative spill over effect reputation-wise; increased challenge of two brands; potential conflict between companies |
| Flanker | Spillover between market segments; increased resources; increased competition; cannibalization |
| New brand | Lack of brand connection; typical new product risks |

entering new brand strategies outperforming late entering new brand strategies. Using the product lifecycle (*see* STAGES OF THE PRODUCT LIFE CYCLE) framework, companies tend to pursue brand growth strategies, particularly line extensions, in the growth stage of the product life-cycle.

CONCLUSION

Table 1 summarizes the five brand growth strategies with respect to core brands and implemented growth strategies. While the benefits of each brand growth strategy are evident in long-term value, Table 2 provides an overview of the possible disadvantages associated with each brand growth strategy. Unfortunately, there are no magic formulas for managing brand growth. Brand growth decisions are judgment calls utilizing both art and science. They are based on an analysis of market situations, company knowledge, and, of course, a hint of intuition. Not surprisingly, all five brand growth strategies are intertwined closely with the product and market lifecycles.

brand strategy

Colin Jevons

BRAND ORIGINS

In the days when livestock roamed free, farmers identified their property by burning an indelible mark on their animals' skins, originally with a piece of burning wood. This practice was named after the Old Norse word for burning – “brandr.” The first Western commercial brand was probably that of Bass beer in England in the seventeenth century, a triangle scorched on the surface of its barrels to certify its provenance from a good, quality-controlled source. But there is evidence of brands in China well before that, with an image of a white rabbit used as a symbol of quality for sewing needles as far back as the Song Dynasty, from 960 to 1127 CE (Eckhardt and Bengtsson, 2007). Just as agriculture has developed since the early days, starting with the development of separate enclosures for animals up to modern-day bar-coded ear tags and RFID, so too has the wider application of branding and brand strategy developed (particularly since the mid-twentieth century) and the concept of a brand being merely an identifying sign, symbol, or device for differentiation is now very outdated. Brand strategies that worked in the twentieth century are becoming less effective in the twenty-first as the nature of brands and how they are cocreated changes (see BRAND GROWTH STRATEGY). de Chernatony (2009) suggests that any definition of brand should include an appreciation of differentiation, positioning, personality, vision and added value in providing a cluster of values that enable a promise to be made about a unique and welcomed experience. In contrast, the *American Marketing Association* offers three definitions on its website: the first definition reads “A name, term, design, symbol, or any other feature that identifies one seller's good or service as distinct from those of other sellers. The legal term for brand is trademark. A brand may identify one item, a family of items, or all items of that seller. If used for the firm as a whole, the preferred term is trade name.” While the second definition includes a reference to the experiential, “a

customer experience represented by a collection of images and ideas,” it focuses mainly on the symbolism of the product offering, and the third definition specifically refers to tangible representations such as logos which can be developed to represent values. Since strategic marketing managers devote more effort to customer-focused activities than to trademarks and logo design, this article will consider strategy as it relates to the customer experience of the brand, following Keller's (1993) principle of customer-based brand equity. This diversity of views shows that any contemporary understanding of “brand” must be highly contextualized (Gabbott and Jevons, 2009), adding complexity to any attempt to define brand strategy.

BRAND STRATEGY

Given this complexity, it may be best to refer to an authority that is as free of contextual bias as possible. The Oxford English Dictionary (1989) reports definitions taken from public usage, and in this way defines strategy in a business sense as a plan for successful action (see MARKETING STRATEGY). Planning the success of brands involves a wide range of actions and therefore a wide range of managerial decisions (see MARKETING PLANNING). Brand strategists must make decisions about brand hierarchies (corporate, family, and individual brand), portfolios of brands, and consolidating and focusing brands in the transition from simple transactional branding toward brand relationships with consumers (see PORTFOLIO MANAGEMENT; CONSUMER INVOLVEMENT). This increased emphasis on relationships is leading to a revival of the conflict between private label and manufacturer brands. The dynamic business and societal environment is increasing the need for managers to be aware of the drivers of brand positioning and repositioning, maintaining a delicate balance between the need for a brand to deliver a consistent message to its stakeholders while still remaining relevant to them (Blumenthal, 2002). Astute brand strategists also must manage the tension between attempting to differentiate the brand while ensuring that it continues to deliver on the performance dimensions most salient

2 brand strategy

to buyers (Ehrenberg, Barnard, and Scriven, 1997). The relationship between brands and their brand extensions is also important, as the extension can affect the parent brand itself – either positively or negatively (see BRAND EXTENSIONS AND FLANKER BRANDS). A further challenge with brand strategy today is that managers no longer have complete control over brand positioning and brand meaning (if they ever did have it; see POSITIONING ANALYSIS AND STRATEGIES). Courtesy of new communications technologies and consumer empowerment, cocreated brand meaning is one of the more pressing challenges facing twenty-first century brand managers, along with consumer-led brand positioning (Beverland and Ewing, 2005; see VALUE CO-CREATION). Thus, brand strategists may at times need to “manage” multiple brand meanings, whereby the same brand may come to mean different things to different stakeholders despite seemingly consistent positioning and marketing communications messages (Berthon, Pitt, and Campbell, 2009). Additional challenges facing brand strategists in the short-to-medium term include managing consumer backlash, anticonsumption, and the rejection of brand hegemony (Cromie and Ewing, 2009), recognizing and managing the inevitability of brand demise: that is, not all brands can nor should be saved (Ewing, Jevons, and Khalil, 2009), and developing more effective approaches to valuing brand equity and brand capability (Ratnatunga and Ewing, 2009, see BRAND VALUE). Finally, the extant literature on brand strategy has a distinctly western, distinctly blue-chip bias. There is still much we need to learn about eastern, for example, Asian, generally (Ewing, Napoli, and Pitt, 2001) Chinese (Ewing *et al.*, 2002) and Indian, approaches to brand management. Similarly, while much has been written about managing Fortune 500 and Interbrand top 100 (largely iconic) brands, less is written about managing brands within small and medium enterprises (Berthon, Ewing, and Napoli, 2008). Thus, despite a reasonably impressive corpus of brand strategy knowledge, there is still a fair amount more for brand strategists and scholars to learn.

brand value

Randle D. Raggio

WHAT BRAND VALUE IS?

Brand value is the sale or replacement price of a brand (Raggio and Leone, 2009). Although brands are valuable to consumers (by reducing search costs and risk) (Barwise, 2003), the concept of brand value most frequently is applied from the perspective of a business that owns, potentially owns, or uses a brand (see PERCEPTION OF BRAND EQUITY for more information about consumer impacts of brands). Brands create value for businesses by positively impacting cash flows through increased revenue (e.g., higher probability of choice, insulation from competitive threat, better acceptance of brand extensions, etc.) or reduced costs (e.g., the ability of certain brands to attract better employees at lower cost, lower cost to introduce extensions) (Raggio and Leone, 2009).

LEVELS OF BRAND VALUE

Two levels of brand value are identified: *Current value* refers to the projected profits of the brand with its current ownership, management, strategies, capabilities, and resources (Raggio and Leone, 2009). *Appropriable value* refers to the theoretical level of brand value that could be achieved if all brand equity were fully leveraged through such activities as brand extensions, pricing, advertising, or distribution (Raggio and Leone, 2009). A firm can choose either to chase the appropriable value of its brand by continuing to own and invest in it; or the firm may choose to sell or license the brand to a firm with stronger brand management skills and a greater ability to leverage brand equity (Raggio and Leone, 2009). Estimates of current value set a floor on the price a firm would accept to sell its brand, while estimates of appropriable value set a ceiling on the price that an acquiring firm would pay.

INCREASING APPROPRIABLE VALUE

Firms increase the appropriable value of their brands by building brand equity (e.g., through patents, endorsements, positive word-of-mouth, etc.), and then chase the higher appropriable

value (thus increasing current value) of their brands by more fully leveraging existing brand equity or by selling or licensing the brand to another firm (Raggio and Leone, 2009). Thus, brand value varies depending on the owner (or potential owner) of a brand, and on the basis of the focal company's ability to successfully chase appropriable value, which is accomplished by leveraging existing brand equity.

APPROACHES TO BRAND VALUATION

Three general approaches to brand valuation exist: cost-based, market-based, or future cash flow-based (Salinas and Ambler, 2009). Cost-based approaches rely on historical costs, but are hampered by the fact that not all brand "investments" are created equal. As such, ROI vary, and an estimate of money spent may not reflect the price to recreate the brand again in the future (Haxthausen, 2009). Market-based valuations attempt to compare a brand against other similar brands that have been sold, licensed, securitized, or valued for other purposes. But since management's ability to chase appropriable value varies, and because brands offer unique benefits to different target segments, market-based estimates must be adjusted for the idiosyncrasies of the focal brand and firm (e.g., size and growth rate of target segment(s), patents, trademarks, etc.). Finally, present values of future cash-flow procedures attempt to determine the portion of cash flows that are attributable to the brand as opposed to the underlying product or other factors (such as distribution efficiencies or other economies of scale/scope).

USES OF BRAND VALUATION

Brands are valued for a variety of reasons: brand valuation can be done to communicate the value of a firm's asset(s) to financial markets, potential buyers, or licensing partners, as a measure of the effects on consumer behavior (e.g., choice, willingness to pay a price premium, acceptance of brand extensions, etc.), or for management purposes (e.g., to gauge the effectiveness of brand managers and brand management strategies or tactics) (Haxthausen, 2009). Brand valuation procedures and estimates can vary depending

2 brand value

on the purpose of the valuation. For example, a cost-based approach may be informative if considering the decision to extend an existing brand versus develop a new one; market-based comparables may help justify licensing fees; and cash-flow based estimates may be important in the sale or securitization of a brand.

bundling

Shikhar Sarin

DEFINITION

Bundling is defined as the practice of marketing two or more products and/or services in a single package (Yadav, 1994). As a strategy, bundling is becoming increasingly popular in marketing, not only for consumer products and services, but also for industrial products (Johnson, Herrman, and Bauer, 1999; Yadav, 1994; *see* PRICING STRATEGY; INTERNATIONAL PRICING OBJECTIVES AND STRATEGIES). However, despite its popularity, much remains to be learned about how to design optimal bundles (e.g., bundle size, bundle price, etc.). This discussion briefly highlights two elements critical to our comprehension of bundling: the process by which buyers evaluate bundles, and how buyers perceive the value of a bundle. We conclude with a brief discussion of some strategic implications of bundling.

PROCESS OF BUNDLE EVALUATION

Early understanding of bundle evaluation was based on an additivity assumption (Yadav, 1994; *see* CONSUMER DECISION MAKING; CHOICE MODELS). That is, the overall utility of a bundle was assumed to be equal to the sum of the individual utilities of the bundled items. This assumption was subsequently discarded. Later research (e.g., Einhorn and Hogarth, 1985; Johnson and Puto, 1987) suggested that buyers evaluate a bundle by averaging the evaluations of individual items in the bundle, and that a weighted average model of bundle evaluation may be more appropriate (*see* CONSUMER DECISION MAKING; CHOICE MODELS).

Yadav (1994) notes that even in a small bundle of very few items, the amount of information to be processed by the buyer can be onerous. As such, buyers are likely to look for heuristics to simplify the evaluation task as a series of smaller (and simpler) evaluations (*see* CONSUMER DECISION MAKING; CHOICE MODELS). Yadav suggests that the anchoring and adjustment heuristic may enable the buyer to accomplish such an evaluation. Anchoring and adjustment

involves an initial assessment (i.e., anchoring), followed by one or more adjustments. Using a series of experiments, Yadav (1994) showed that an anchoring and adjustment process of bundle evaluation involves three stages:

1. *Scanning stage*: where buyers determine which items are contained in a bundle. No evaluations are made at this stage.
2. *Anchor selection stage*: where buyers initiate the evaluation process by selecting one bundle item perceived to be the most important item for the evaluation task.
3. *Anchoring and adjustment stage*: where using the evaluation of the anchor as a starting point, the buyers initiate the evaluation of the bundle by evaluating the remaining items in the bundle in decreasing order of perceived importance. The buyers adjust their initial anchor evaluations upward or downward to reflect the new information.

Researchers (e.g., Einhorn and Hogarth, 1985; Johnson and Puto, 1987) note that bundle evaluations produced using the weighted average approach are very similar to those produced using the anchoring and adjustment method, suggesting that both these approaches capture the compensatory process of bundle evaluation in consistent but complementary ways (Yadav, 1994).

VALUATION OF A BUNDLE

In addition to the process of bundle evaluation, the perceptions of overall savings (*see* A FRAMEWORK FOR CREATING VALUE PROPOSITIONS; VALUE PROPOSITION) from the bundle are critical to the design of optimal bundles. Yadav and Monroe (1993) suggest that buyer's perceptions of overall bundle savings consist of two distinct perceptions of savings:

- perceived savings on the individual items if purchased separately, and
- perceived additional savings on the bundle.

Yadav and Monroe show that the additional savings offered directly on the bundle have a

greater influence on the buyer's perceptions of the transaction value, compared to the savings offered on individual bundle items. Others however suggest that more positive evaluations of a bundle are likely to result if the component prices are integrated into a single price, but the component discounts are segregated into a set of discounts (Johnson, Herrman, and Bauer, 1999). That is, buyers were likely to be more satisfied with bundles and more likely to purchase and recommend them, if the pricing information was bundled and the price discount information was unbundled.

Johnson, Herrman, and Bauer note that large gaps exist in our understanding of how best to present bundled price information to the buyer. Clearly, contradictory pricing guidelines such as those illustrated above, point to a need for additional exploration of this phenomenon.

STRATEGIC IMPLICATIONS OF BUNDLING

While much of the bundling research has focused on bundle evaluation and price bundling, recent research (e.g., Bakos and Brynjolfsson, 1999, 2000; Sarin, Sego, and Chanvarasuth, 2003) points to larger strategic implications of bundling. In addition to the increase in sales documented in earlier research, emerging research points to the use of bundling to market high-tech products. For example, Sarin, Sego, and Chanvarasuth (2003) suggest that bundling could be used as a strategy to reduce the perceived risk associated with the purchase of new-high tech products, and hence increasing their adoption and acceptance. They offer a series of recommendations for the optimal design of bundles for new high-tech products.

Similarly, Bakos and Brynjolfsson (1999) show bundling a large number of unrelated information goods to be very profitable. Bakos and Brynjolfsson demonstrate that the law of large numbers makes it much easier to predict the customer's valuation of a bundle of goods, as compared to their valuations of

individual good when sold separately. This "predictive value of bundling" makes it possible for the seller to extract more value from each information good through greater sales, greater efficiency, and greater profits from a bundle of information goods, than can be attained from selling them separately (Bakos and Brynjolfsson, 1999, 2000). Bakos and Brynjolfsson suggest that large aggregators of information goods can be more profitable than small aggregators by offering a menu of different bundles, aimed at different market segments, increasing the impact of traditional price discrimination strategies.

communications budgeting

Richard F. Beltramini

Communications budgeting refers to appropriating the human, financial, and physical resources needed to support the integrated marketing communications (IMC) activities of an organization, and then allocating these resources among the various IMC components (e.g., advertising, public relations, sales promotion, etc.). While this is a slightly complicated and inexact process, a number of commonly accepted budgeting methods are typically used today (see Arens, Weigold, and Arens, 2009 and others).

The “*percentage (of sales)*” method is perhaps the simplest communications budgeting method to employ. Organizations simply appropriate a percentage of their revenues to support the IMC function, ranging from a small percentage among, for example, industrial equipment or technology companies, to sometimes as much as 20% among alcoholic beverage or cosmetics manufacturers. Unfortunately with simplicity comes the slightly arbitrary assumption that all competitors are in identical positions, and typically the backward reliance on sales experience rather than driving future marketplace response.

Another communications budgeting method is the “*share (of market)*” technique in which organizations appropriate resources according to their desired share of market activity. Particularly for new-product introductions, a multiplier of desired share is often used initially (e.g., if a 10% share of market is desired, perhaps a 15% share of all resources expended by all competitive brands in its product category may be allocated for the product introduction period). Obviously, for this approach to communications budgeting to work, organizations must have knowledge of all competitors’ IMC activities.

Finally, the “*objective*” method represents the most sophisticated communications budgeting approach, first developing quantifiable marketing communications objectives (what to accomplish), then strategies (what to do), and finally tactics (how to do it). For example, if an organization decides to “increase brand awareness by 10% among Midwest teens,” it

might want to strategically position the brand as offering the “best taste in the product category,” and analyzing what media mix (e.g., broadcast, print, online, etc.) is needed to get that message communicated to its target audience. This approach builds up resources needed based on activities required to accomplish measurable market responses.

A number of factors obviously influence the selection of a communications budgeting method. For example, the reality of an organization’s financial situation may ultimately limit the amount indicated by one of these methods, the seasonal timing and product life cycle of competing brands may dictate the need for accelerated (or decelerated) marketplace activity, and the availability of market intelligence may vary between simple intuition (or habit) and sophisticated empirical assessments of competitive activity and forecasted demand. In some cases, organizations might find it necessary to simply match what competitors are doing, while in other instances, a series of performance metrics might be used to map out a series of test-evaluate-retest refinements.

The most important element of communications budgeting, however, remains a solid understanding of the role of integrated marketing communications in effecting marketplace response. Communications activities alone or in combination do not simply *cause* market impact (awareness, interest, desire, or action). In fact, a myriad of controllable and uncontrollable factors complicate the relationship between say, a product advertisement run and the product sales afterward. While no one communications budgeting method is appropriate in all instances, individual selections require both a grasp of the theory behind how communications work and the practice of flexibility in the face of uncertainty.

cannibalism

Dwight R. Merunka

SALES CANNIBALISM

New-product sales require market expansions, stolen sales from competing products, or cannibalism of sales of the firm's own products. Sales cannibalism is the extent to which a new-product's sales (or a current product's sales) come at the expense of other products offered by the same firm. It, thus, can be measured as the proportion of a product's sales drawn from product(s) of the same brand or made by the same manufacturer (Mason and Milne, 1994). In mature markets, new products do not attract new customers nor increase consumption rates among current customers. Therefore, a high proportion of sales of new products likely come from the cannibalization of the firm's existing products. In general, the extent to which cannibalization occurs depends on product substitutability or "substitutability in use," a concept that holds that products are regarded by consumers as interchangeable for some relevant purpose or usage situation.

According to this perspective, marketers generally consider sales cannibalism an outcome of improper product positioning and management (*see* POSITIONING ANALYSIS AND STRATEGIES). That is, cannibalism is something to avoid, because it is not desirable to lose market share or sales of profitable existing products when introducing a new one. Cannibalism represents a potential problem and a negative consequence of new-product development, as is well illustrated by channel cannibalization, or sales losses in existing channels as a result of penetrating a new one. In fact, fear of cannibalization has deterred many firms from deploying the Internet as a distribution channel (Deleersnyder *et al.*, 2002). However, in the context of radical product innovation, assuming that cannibalization is negative and should be avoided at all costs may be dangerous and risky.

WILLINGNESS TO CANNIBALIZE

Cannibalism can also be viewed as taking an initiative to supersede the firm's existing

products before a competitor's entry attacks them (Conner, 1988). Therefore, the decision involves whether to cannibalize planned sales and profits on existing products by introducing a new product whose anticipated performances remain largely unknown. This conceptualization of cannibalism is particularly important for radical product innovations (*see* RADICAL INNOVATION). Because radical product innovations can result in substantial cannibalization of existing business, Chandy and Tellis (1998) argue that a positive disposition to cannibalize the firm's current resources represents a key variable to explain the firm's level of radical innovations.

Willingness to cannibalize is "the extent to which a firm is prepared to reduce the actual or potential value of its investment" (Chandy and Tellis, 1998, p. 475). It entails a multidimensional construct: Firms can cannibalize (i) investments in the form of assets (equipment, technology, knowledge, expertise), making prior investments obsolete; (ii) organizational capabilities (established procedures) that will render skills and routines obsolete; and (iii) sales, which require introducing new products that will diminish the sales of current products (Nijssen, Bas, and Vermeulen, 2005). A company's willingness to cannibalize explains why some companies develop more radically new products than do others (Chandy and Tellis, 1998). In this sense, it is a desirable trait that promotes radical product innovation and the long-term success of the firm.

Firms making substantial sales and profits with their current products may be reluctant to introduce new products if they fear they will be cannibalizing their current sales and prior investments. However, willingness to cannibalize drives radical product innovation, and firms must be willing to cannibalize before the obsolescence of their current products occurs – at which point there will be nothing left to cannibalize.

competitive advantage: its sources and the search for value

Albert Caruana

The concept of competitive advantage highlights the close interlink between marketing and strategy. Strategy seeks to relate a company to its environment and to determine where the manager wants the business to go. To get there managers need to identify an activity or activities that can collectively offer value to customers. In the book *Competitive Advantage*, Michael E. Porter (1985, p. 3) makes this point clear and states that “Competitive advantage grows out of the *value* a firm is able to create for its buyers that exceeds the firm’s cost of creating it.”

Value lies at the core of marketing. This is what customers look for and are willing to pay for. The pivotal role of value has long been recognized in marketing and is reflected in the more recent definition of marketing, which the American Marketing Association (2007) declares as “the activity, set of institutions and processes for creating, communicating, delivering, and exchanging offerings that have *value* for customers, clients, partners, and society at large.” Value is not an absolute but a relative concept recognizing that new competitive offerings may erode any value offering that the firm may have in the market (see CUSTOMER SOLUTIONS).

Value must necessarily be considered from the customers’ perspective, yet unfortunately many organizations fail precisely in this regard. There are numerous reasons for this. A focus on manufacturing or distribution may lose sight of the ultimate beneficiary for whom these activities are being undertaken, while with service offerings value is often defined by the professional with little focus on customers. Indeed, medical practitioners look at their clients as patients, which by definition implies that they often need to be just that – patient!

This contribution highlights the salient role played by value and how it underpins the identification of viable sources of competitive advantage. It commences by taking into account the centrality of cost leadership and differentiation as two important sources of competitive advantage. These interact with particular target

markets to provide three main generic strategies. Marketing advantage is then considered as a further basis of competitive advantage and while discussing cost leadership and differentiation advantage, a typology is investigated that explicates major sources that sustain each of these advantages. This is followed by consideration of how the value chain enables the identification of activities that underline a particular value offering that underpins the different types of competitive advantage that the firm can provide. Finally, the main generic strategies are discussed while attention is also drawn to other perspectives on competitive advantage. In conclusion, the point is made that the various available frameworks are best viewed as aids and not as substitutes for management thinking on competitive advantage.

GENERIC STRATEGIES AS SOURCES OF COMPETITIVE ADVANTAGE

To provide value once is not sufficient and competitors will act to erode any advantage a firm may have, often via imitation and *innovation* (see INNOVATION DIFFUSION). For a competitive advantage to be real it must endure over time. When an advantage can be maintained over time it is said to be *sustainable* and managers can talk of a sustainable competitive advantage. For sustainability to exist, the relative advantage that the positioning achieves needs to have meaning for target customers (see MARKET SEGMENTATION AND TARGETING).

The challenge for managers is to identify the sustainable competitive strategy that will underpin the direction that they will pursue for their firm or for their product. Porter (1985) argues that there are two main sources of competitive advantage that he terms *cost leadership* and *differentiation*. Competitive advantage is possible by either pursuing a low-cost positioning or by underscoring differentiation that involves emphasizing some perceived uniqueness that exists or can be fostered among customers. Alternative positioning for the firm can be achieved relative to other players in an industry depending on the choice of strategic target (or competitive scope) in terms of whether the firm pursues a broad industry-wide target or whether it targets a narrower segment.

2 competitive advantage: its sources and the search for value

| | | Competitive advantage | |
|-------------------|---------------|-----------------------|-----------------------|
| | | Lower cost | Differentiation |
| Competitive scope | Broad target | Cost leadership | Differentiation |
| | Narrow target | Cost focus | Differentiation focus |

Figure 1 The three generic strategies. Source: Porter (1985, 12).

These two dimensions of competitive scope and competitive advantage are utilized in a matrix to highlight the three potential successful generic strategic approaches achievable. Depending on the target market focused on, it is possible to identify three successful generic strategies that can enable the firm to outperform competing firms in an industry. These include the following:

1. Overall cost leadership
2. Differentiation
3. Focus.

Overall cost leadership and differentiation are positioning decisions that can have meaning for broad targets, while narrow targets require focus on either cost or on differentiation as depicted in Figure 1. Each positioning can provide a competitive advantage and represents a unique value offering to customers that allows different firms to compete in the same industry without being in direct competition with each other at most times.

It is clear that no firm, in whatever industry, can offer value and be all things to all people. To achieve a sustainable competitive advantage, the firm needs to make choices that can offer value to customers and that value must not be easy to imitate by competitors. Such value may arise from offering customers great service as a result of customer-centric delivery processes that are not easy to replicate. Value may also come from very efficient operating systems that are able to squeeze out costs and pass some of that value to customers. The search for value offerings is ongoing in all competitive industries.

The airline industry offers a good example of these strategies at work. In this industry, there has been an ongoing struggle to target and differentiate broad groupings. This has been pursued by players such as British Airways who have used full service differentiation throughout the organization in their Putting People First programs, calling themselves “the world’s favorite airline” in an attempt to differentiate on a basis that goes beyond the British nationality factor that can offer only limited differentiation. On the other side of the cost leadership matrix, the entry of low-cost airlines such as Ryan Air and Easyjet underlines the pursuit of a positioning that has witnessed the erosion of customers away from the many airlines that previously sought a differentiated positioning. In addition, within the industry, there are many examples of small regional airlines that necessarily target narrowly and can compete on cost with the more differentiated airlines on particular routes. Before its demise, Volareweb that operated from Italy to select European routes sought to compete on price. However, it is also possible to target narrowly by focusing on routes that are not well served as between Rome and Lugano, Switzerland where Darwin Airlines can pursue a more service-quality-differentiated focus strategy.

Best (2004) recognizes cost advantage and differentiation advantage as the two primary sources of competitive advantage but also adds marketing advantage as a third source of competitive advantage. This involves marketing activities that make it possible for the firm to dominate competition on the basis of sales, distribution, or brand recognition, or some combination of these three. In addition, these three categories are used to provide a useful typology that clarifies the activities by which a business can achieve a competitive advantage. The typology seeks to drill down on each of the sources of competitive advantage by considering three variations under each category (Figure 2).

Cost advantage. The competitive advantage typology is useful and its three main variations are now discussed. We start by first looking at cost advantage, which arises when the business is able to generate economic value by having

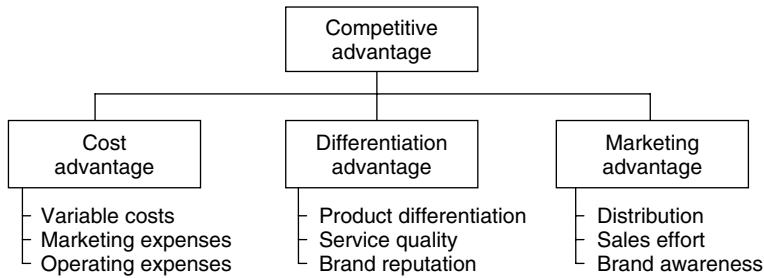

Figure 2 Major sources of competitive advantage. Source: Best (2004, 140).

costs that are lower than those of competitors. The three main sources of cost advantage are reviewed.

Lower variable costs. Lower variable costs can result in lower prices or higher margins relative to competitors. One of the most common ways in which a firm can achieve lower variable costs is via economies of scale. A firm with a large MARKET SHARE is able to achieve purchasing efficiencies and lower the cost of production and can enable costs to be split across a larger output (see BRAND GROWTH STRATEGY). Such a position precludes competitors from gaining market share as it will be difficult for such firms to achieve the necessary volume to match unit costs. Large volume production can also benefit from a learning curve effect where not only do unit costs decrease because of growth in the volume of production but there is also a further drop that results from a learning effect. This comes about because, with practice, people and organizations become better at their tasks, thereby increasing the efficiency of production making it possible to cut unit costs even further. Typically, learning curves follow a negative exponential distribution.

Marketing cost advantage. Marketing cost advantage results from a marketing cost scope effect whereby the various costs of marketing can be divided over a broader range of outputs as a result of extensions in product breadth and/or width. The pursuit of umbrella branding is a case in point. In contrast to individual product branding, umbrella branding is especially widespread among service firms, including banks. Such firms can gain from economies of scope, in this case, with respect to advertising,

whereby a single advertising campaign can be employed to promote an entire range of product offerings. It is possible to derive a marketing cost advantage not just from lower advertising costs but also from other marketing activities.

Operating cost advantage. Operating costs refer to the expenses involved in running a business that is not directly related to the production and sale of the current line of goods or services. These include such costs as the general and administrative expenses involved in running a business which, if they can be lowered, can also provide a low-cost advantage. The new Airbus A350XWB scheduled to come into service in 2013 is a wide-bodied aircraft that competes with the Boeing 777 and 787. The manufacturer claims that the A350XWB will be able to offer airlines buying the aircraft “a 20 per cent lower cash operating costs per seat than competing aircraft in this size category and fuel efficiency improvements of up to 25 per cent per seat.” In addition, it has been reported that Airbus has been looking at putting a 10-abreast instead of a 9-abreast seat configuration allowing the operating cost per seat to be such that it could not be matched by any other aircraft.

Since not all businesses are able to have some type of cost advantage, managers can consider seeking a differentiation advantage as their source of competitive advantage. *Differentiation* (see POINT OF DIFFERENCE AND PRODUCT DIFFERENTIATION) represents a second alternative competitive advantage to the firm that arises when the business is able to generate economic value by giving a product offering that customers prefer over competitors’ product offerings. A differentiation advantage is possible

4 competitive advantage: its sources and the search for value

on practically any basis as long as it can meet some customer need or needs better than those of competitors. The three main sources of differentiation advantage are elaborated.

Differentiation advantage.

Product advantage. The product offering provides various attributes that allow for differentiation. While an exhaustive list is necessarily elusive, it is possible to provide a few examples that can give an indication of the possible alternatives available. Thus appearance, design, and features have been used by Apple to strongly differentiate their offerings. Product features have been used effectively by Toilet Duck where its original duck-shaped dispenser for toilet cleaner designed to reach under the rim of toilets was able to provide a distinctive *positioning* (see POSITIONING ANALYSIS AND STRATEGIES) in the detergent market. Product benefits are also widely used for the purpose of differentiation with the toothpaste market offering a good example with brands like Sensodyne for sensitive teeth and Crest against tooth decay clearly emphasizing different benefits to consumers.

Service advantage. Attribute characteristics that can provide a differential advantage to tangible products can also be leveraged for intangible or *service* products (see CONSUMER BEHAVIOR AND SERVICES MARKETING). Indeed most offerings in the market can be seen as representing a combination of the tangible and the intangible. However, the aspect of service quality is an area that has enabled differentiation among the more intangible offerings in the market and has received much research attention. Often defined as the difference between expected and actual performance, it has been shown that service quality has beneficial consequences in terms of customer satisfaction, loyalty, and ultimately profitability. Service quality is seen as encompassing dimensions of reliability, responsiveness, assurance, empathy, and tangibles. Service quality is demanding to be put in place and, if done successfully, can provide a service firm with a differential advantage. Singapore Airways is the only one in a handful of airlines that gets a five-star rating from SKYTRAX, the airline and airport

quality certification firm, which confirms that Singapore Airways provides a high-quality service experience to passengers.

Reputation advantage. Reputation can be considered at both a product and at a corporate level. It is an aspect that is also able to provide the firm with a competitive advantage. Like service quality, building a reputation is demanding and it cannot be easily copied. While brands can be thought of as symbols around which relationships can be built between sellers and customers, brand and corporate reputation is essentially a feeling or a disposition to respond favorably or unfavorably to a brand or company. However unlike brands, reputation extends beyond customers and can vary by different communities or publics. Thus, while Abercrombie & Fitch is undoubtedly a strong brand that sells a lifestyle image popular with teens and young adults, the brand and its corporate reputation among some noncustomer groups and other communities have seen some of these noncustomer publics raise questions about such things as the quality of the clothes and the advertising approach adopted by the brand. On the other hand, Google is able to have a strong reputation among different publics. In its reputation, it possesses an asset that can provide various benefits to the firm. Therefore, its reputation advantage can result in increased sales; can foster more credible advertisements; can improve perceived product quality; can produce higher customer loyalty; can add value; attract higher margins, and increase cash flow and profits. It can also attract investors and high-quality job applicants.

Marketing advantage. Besides pursuing a cost or a differentiation advantage as their source of competitive advantage, it is possible for a firm to gain competitive advantage by leveraging a combination or a particular marketing strength relating to sales coverage, distribution, or brand recognition. These three aspects are further elaborated as follows:

Channel advantage. The ability to gain distribution coverage or to deny coverage to competitors is an important competitive advantage that goes beyond cost or a differential advantage. Cisk, a dominant market share lager

brand in Malta that came under increased competition from a new local brewery that bottled Lowenbrau, was able to counter the new competition by effectively denying access to the distribution network to the competitor. It succeeded by using pricing and sales promotion activities directed at the distribution.

Sales force advantage. There are four key strategic sales force challenges that need to be met, which, if they are successfully tackled, can provide the firm with a competitive advantage. These relate to: how many sales people should be employed; whom they should visit, and with what frequency, and how the sales force should be organized. If met properly together, these can provide the firm with a sales force that is effective and can also afford superior coverage to that of competitors with sales forces that are larger or of comparable size.

Brand awareness. Brand awareness refers to the level of recognition that customers have of a brand together with knowledge of the specific product category to which it appertains. With many fast-moving consumer goods where the difference among products is marginal, brand awareness plays a very important role. Colas are a case in point. The differences in the colas at a taste level are relatively minor but brand awareness for the likes of Coca-Cola and Pepsi, together with the image they portray, results in higher sales for these brands and provides a significant barrier that precludes other colas from gaining market share. The brand awareness of these two brands effectively provides them with a competitive advantage irrespective of possible superior qualities in terms of attributes such as taste or price that other competing colas may have.

VALUE CHAIN, VALUE PROVISION AND COMPETITIVE ADVANTAGE

Porter (1985) sets out the concept of the value chain as a useful framework that describes how the organization undertakes certain activities that are able to create total value and uphold a particular competitive advantage. Any firm can be thought of as a set of limited resources that makes use of activities to provide value that

enables the firm to earn a margin. Margin is generated when created value exceeds costs.

The value chain allows management to systematically consider the various activities involved. The primary activities in the value chain that enable the firm to make its offering are inbound logistics, operations, outbound logistics, marketing and sales, and service, while support activities consist of firm infrastructure, human resource management, technology development, and procurement. The latter three can support each of the primary activities while firm infrastructure acts to support the entire chain (Figure 3).

The value chain highlights the fact that value can be provided not just from the products and brands (*see* BRAND VALUE) that the firm makes available but also from effective procurement and the channels of supply and distribution. The activities that are brought together in the value chain allow value to be provided to customers, determining the differentiation that can take place, and the costs that will ultimately result. One needs to understand how these activities are being utilized, how they are controlled, and how they interact, with a view to devising ways so that they can be used to gain competitive advantage.

Analysis of the elements of the value chain underlines the search for synergetic effects that can result from the extra benefit that can be derived by the firm by not only looking at the elements of the value chain but also by bringing together the added value the different linkages in the value chain are able to provide. Competitive advantage results because the firm is able to undertake these activities more effectively or at a lower cost than competitors.

The value chain is not without its critics and it has been argued that the mental framework behind it appears to assume a manufacturing rather than a service entity. In addition, it appears to betray an assembly-line likeness in its linear, sequential, and unidirectional focus.

ALTERNATIVE GENERIC STRATEGIES

Porter (1980, 1985) cautions against a failure to opt for one of the three alternative generic strategies and describes firms that fail to pursue one of the three generic strategies as “stuck in the middle.” It has been suggested that such

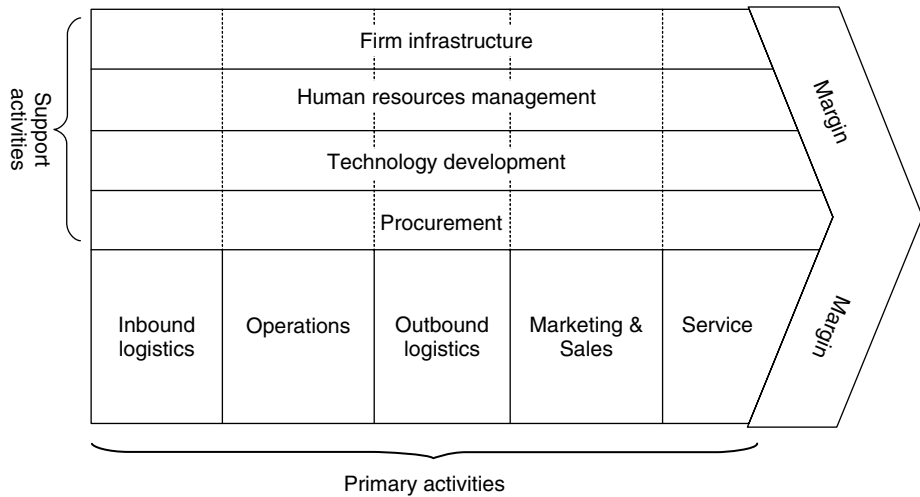

Figure 3 The generic value chain. Source: Porter (1985, 37).

firms are unable to use their resources effectively and consequently can be expected to exhibit poor profitability. While accepting temporary situations where the pursuit of both a cost leadership and a differentiation strategy can be possible, firms are encouraged to look at their resources and determine the strategic orientation that can best be matched to their capabilities. It is therefore argued that firms cannot simultaneously pursue a cost leadership and a product differentiation strategy. Rolex, which pursues a narrow differentiated focus positioning, is a case in point. Its structures, management control, and compensation policies preclude the pursuit of a cost-focused positioning.

However, it has been suggested that the generic strategy positions may not always be as mutually exclusive as suggested. Hill (1988, 401) has argued that “the circumstances in which the simultaneous pursuit of differentiation and low cost make sense are common, depend on more factors than previously highlighted, and may well lead to the establishment of a sustainable competitive advantage.” A contingency framework is therefore proposed where, in the circumstances of certain emerging and mature industries with particular characteristics, managers can successfully pursue a sustainable competitive advantage that can frequently involve the simultaneous pursuit of differentiation and low-cost strategies.

A similar point is made by Miller (1992) who argues against the notion of “stuck in the middle” and holds that a strategy that straddles both positions is viable. Therefore, Caterpillar Inc., which pursued a differentiated strategy that focused on providing earth-moving equipment with distinctive characteristics in terms of high precision and durability while paying less attention to efficiency and economy, enabled Japanese firms to undercut them on price by 30% – the point being that overspecialization and differentiation of the offering can omit important attributes that customers are also looking for and that may afford an opportunity that can be exploited by competitors. Toyota would seem to be an example of a firm that has been able to pursue both a cost leadership and differentiation strategy simultaneously. This is possible because some bases of differentiation have been able to also lower costs. The structures, policies, and controls employed are complementary, and enable such a stance to be possible.

The debate as to the relevance of generic strategies is ongoing. A number of authors have suggested that cost leadership and differentiation strategies are too generic and are limiting. Kim and Mauborgne (2005) look at what they call *value innovation* and argue that a firm should look outside their current paradigms to find new value propositions (see A FRAMEWORK FOR

CREATING VALUE PROPOSITIONS) in new market space or “Blue Ocean.” The pursuit of a Blue Ocean strategy argues against a firm competing in the current market but rather to identify a market demand that has not yet been met.

More recently, Gurău (2007) notes the increased complexity of the current competitive environment that firms operate in and argues for the need for stronger relationship marketing among firms that can build a competitive advantage based on customer loyalty. He envisages management seeking to move their relationship with customers along a continuum from a weak to a strong relationship and suggests employing different aspects of generic strategies, starting with cost leadership in situations of weak relationships and progressing to product quality-based differentiation, support services-based differentiation, a niche strategy, personalized marketing, and ultimately value cocreation in the strong relationship condition on the continuum. Gurău sees relationships, which enable individual customers to cocreate unique experiences as a result of high quality interaction, as increasingly becoming an important source of competitive advantage to the firm.

While success can indeed come about by the adoption of one of the generic strategies, there are circumstances where a mixed strategy that combines elements of both cost leadership and differentiation strategies or a progression of generic strategies on a relationship continuum, can possibly represent a viable alternative way forward. Porter’s generic strategies are not a substitute for management thinking. Matrices

are by their very nature simplistic and reality is often not two-dimensional but multidimensional and complex. Rather, generic strategies and their related matrices should be viewed as aids to thinking that can provide useful insights and indications of possible options for management action in the pursuit of competitive advantage.

competitive analysis

Venkatesh Shankar

INTRODUCTION

Competitive analysis refers to the evaluation of strategies relating to a focal brand, product, strategic business unit (SBU), or firm relative to the current and potential competitors in its market or industry. Competitive analysis can be done at the product-market level, the SBU level, or the firm level. The main purpose of competitive analysis is to develop business and marketing strategies that take into account competitive considerations.

Competitive analysis is typically performed on an ongoing basis. Competitive analysis is conducted before the formulation and development of positioning or value proposition strategy and marketing mix strategies. It is also undertaken for a new brand or product, in particular, prior to its launch in a new market. As such, it is the basis for the development of competitive marketing strategy.

The terms, *competitive analysis* and *competitor analysis*, are used interchangeably. Strictly speaking, competitive analysis is related to but different from competitor analysis. Competitor analysis involves the study of competitors' strengths and weaknesses. It provides key inputs to competitive analysis. Competitor analysis focuses on competitors, whereas competitive analysis focuses on own brand, product, SBU, or firm.

In formulating brand or product positioning strategy, customer perceptions of the focal brand's strengths and weaknesses relative to competitors in a given product market form the inputs for deriving a perceptual map for that market. Using this information and data on the location and size of customer preferences, a brand or product can develop its positioning strategy. Thus, competitive analysis helps a brand or product differentiate itself from competing brands or products.

A good competitive analysis should evaluate the focal brand, product, SBU, or firm relative to both existing and potential competitors. Future competitors include marketers of substitute products and those with alternative technologies

capable of satisfying customer needs in the relevant markets or industries. Competitive analysis is performed at intervals of a year or less.

At the industry level, competitive analysis is typically performed using the five-forces model (Porter 1980, 1985). The five forces that shape industry profitability include threat of new entrants, threat of substitute products, bargaining power of suppliers, bargaining power of buyers, and competitive rivalry. In this analysis, the factors that influence each force are identified and an assessment is made on the level of influence of each force on industry profitability. An overall evaluation of the attractiveness of the industry is reached on the basis of the relative influences of the five forces.

Competitive analysis is also a useful tool for deciding whether, when, and how to introduce a new product in a market. Firms typically decide to launch products when their strengths relative to their competitors outweigh their relative weaknesses in markets where opportunities surmount threats.

AN EXAMPLE OF APPLICATION OF COMPETITIVE ANALYSIS FOR A NEW PRODUCT

Consider the example of competitive analysis for iPhone's marketing strategy before its introduction in 2007. iPhone's key strengths can be analyzed along six dimensions: innovativeness, compatibility, ease of use, brand awareness, price, and quality. The iPhone had an innovative touch screen that is patented and unmatched by other mobile products at the time of introduction. It offered multiple functions in a single mobile device. It was compatible with iTunes, other Mac products and operating system software tools, and other Apple products like Apple TV. It allowed wireless connectivity to the big screen. Its touch-screen interface was easy to use and its operations were intuitive. It was radically different from other phones or personal digital assistants (PDAs) in that it recognized multi-finger gestures common with a normal human hand. Apple was well known for cool essential gadgets like iPods and Macintosh. iPhone initially planned to sell at a reasonable price for its value. The first iPhone was of high

2 competitive analysis

quality as it had one of the brightest and most scratch-resistant screens.

iPhone's key weaknesses were related to targeting, price, and user interface. The iPhone and Apple products, in general, had not been targeted at business people, whom most smart phones had targeted. It did not have a reputation as being compatible with the corporate world. iPhone did not offer lower priced models for price-sensitive consumers. Finally, the touch-screen interface suffered from the problem of "gorilla arm," a condition in which the long-term use of a flat, solid surface for input is uncomfortable for users.

iPhone's key competitors at the time of its launch included Blackberry, Palm, and Microsoft. Although Blackberry was targeted at corporate users and iPhone was directed at individual users, in terms of functionality and features, Blackberry was a close competitor. Blackberry's major strengths were that it catered to a large pool of corporate users and offered reliable email and voice capabilities on the go. The mobile hi-speed Internet connectivity was fairly robust and it was the first to offer corporate email on the mobile device that boosted office productivity. However, it had its own drawbacks as well. The scrolling feature and the keypad for data entry were cumbersome with limited capabilities.

Palm was also viewed as a direct threat in the handset market. With a long history in PDA market and experience in developing software for mobile devices, Palm is a well-known brand for businesspeople. Its software was well established and compatible with many products in that market. There were significant costs for Palm users to switch to iPhone. Palm's major weaknesses were that it was not known for groundbreaking innovations or consumer products. The Palm Treo had a lower quality perception and its interface harder to use, being from an older generation of products and unfamiliar to Apple customers. Furthermore, according to product reviews, Treo's keyboard was perceived to be small and difficult to use, especially for accessing the Internet. Although some users may have preferred having a keyboard built into the device, potential users showed a preference toward using the touch screen.

Microsoft was considered an indirect threat because it provided only the operating system for mobile devices and was in the process of introducing multifunctional mobile devices. Microsoft's major strengths were its financial flexibility and high cash holdings that could be used to develop new products and react aggressively to competition. Microsoft software, the Windows CE operating system for mobile devices, was already "proven" in the marketplace. Microsoft had global brand recognition in software products, in particular, in business markets. Businesspeople were likely to order its products on the strength of its name, whereas Apple did not make devices for business use. Microsoft's key weaknesses were its failed portable music player, Zune, the lack of cool image typically associated with Apple's products, and unexciting customer satisfaction rates.

On the basis of an analysis of iPhone's strengths and weaknesses relative to those of its competitors, Apple decided to launch iPhone by targeting individual users, positioning around its touch screen, easy-to-use innovative features, and compatibility with multiple software applications, projecting a hip image, pricing it at \$599 at the retail, and selling it exclusively through AT&T, the largest wireless operator and well-entrenched brand name. The competitive analysis enabled iPhone capture the hearts of the market but it also revealed problems with its pricing. Within months of the launch, Apple had to drop iPhone's price by about a third and even offer credit notes and refunds to the initial buyers.

GAME THEORETIC COMPETITIVE ANALYSIS

Advances in game theory have provided new tools for competitive analysis. The concepts of game theory can be applied to study competition in marketing variables and predict market outcomes. In game theoretic models, players (firms and/or consumers) play a noncooperative game in which they choose their strategies. A firm's strategy is a complete specification of its actions in all contingencies.

Game theoretic models assume that firms are rational and intelligent. Rationality refers to the firm's maximization of subjective expected utility (profits) and intelligence refers to the

firm's recognition that its competitors are rational. Game theoretic models can be analyzed by solving for equilibrium strategies. Equilibrium is that condition from which no competitor has an incentive to unilaterally deviate from its strategy. In other words, equilibrium strategies are those for which the competitors obtain the best outcomes in the given conditions.

The first step in game theoretic model is specification of the rules of the game. These rules include the number of competitors, the set of feasible strategies or decision variable(s), the profit function, whether it is a one-period (one shot) or multiperiod game, whether one competitor is a leader or follower in the decision variable(s), and the information known to the competitors at different stages of the game. Some information such as which competitor moves first is known to all the competitors and is known as *common knowledge*. If all information is common knowledge, then the game is known as a game with *complete information*. Some information such as manufacturing cost can be known to the focal firm but not to its competitors and is therefore, labeled *private information*. In this case, some rules of the game are not common knowledge, so this game is known as a game with *incomplete information*.

Information can be symmetric or asymmetric. In the case of information symmetry, all competitors are similar in their information knowledge. In the case of information asymmetry, Competitor A may know information on a variable (say cost) about Competitor B, but Competitor B may not have the information on the same variable about Competitor A.

Different types of game theoretic models exist for analyzing different conditions. For example, a game in which one competitor is a leader and another is a follower is known as a *Stackelberg game* and the corresponding equilibrium is known as the *Stackelberg equilibrium*. In contrast, the equilibrium corresponding to a game in which all competitors move simultaneously is known as the *Nash equilibrium*. For the possible existence of both these equilibria, see Shankar (1997).

Game theoretic models exist for analyzing competition in product, price, distribution channels, advertising, and promotion (for a detailed review, see Moorthy 1985). While

much of game theoretic analysis is based on noncooperative interdependence among competitors, there is also cooperative game theory that examines the collusive behavior of firms in certain situations. The predictions of game theory models can be tested through empirical analysis. While game theoretic models are powerful tools for competitive analysis, they have some limitations as well. These limitations include unrealistic assumptions about the game and inability to capture real-world phenomenon through tractable models.

COMPETITIVE ANALYSIS AND REACTION TO NEW-PRODUCT ENTRY

A new product's market success depends on its entry strategy as well as the response of competitors to its entry. Competitive analysis relating to reaction to new-product entry involves a solid understanding of the determinants of new-product entry strategy, its interrelationship with competitor response, and the drivers of competitor response – all of which can be analyzed through a framework proposed by Shankar (1999). According to this framework, a new product's entry strategy and competitor response are determined by entrant, incumbent, and market/industry characteristics. A new-product entry strategy is reflected by decisions on marketing variables such as product line length, price, advertising, and distribution. New-product entry strategy involves competitive considerations, and competitive advantages for pioneers and late movers under different conditions have been well documented (e.g., Shankar, Carpenter, and Krishnamurthi 1998, 1999). The literature on order of market entry in general is extensive (for reviews of order of entry effects in physical and electronic markets, see Kerin, Varadarajan, and Peterson, 1993; Varadarajan, Yadav, and Shankar, 2008).

To better analyze competitive response to new entries, we can use normative and descriptive models of response. A number of normative or game theoretic models of incumbent reaction exist. A seminal analytic model by Hauser and Shugan (1983) shows that it is optimal for an incumbent to decrease advertising and distribution spending in response to a new-product entry

4 competitive analysis

in a static market. Their model also shows that if the consumers' tastes are uniformly distributed, then the optimal competitive strategy is to decrease prices, improve product quality, and reposition the brand more along the incumbent's strength.

A decoupled response function (the effects of advertising and distribution are decoupled) model by Kumar and Sudarshan (1988) shows that the optimal defensive strategy for incumbent competitors is to decrease price, advertising, and distribution when tastes are uniformly distributed and the market is static. A refinement of this model by Gruca, Kumar, and Sudarshan (1992) shows that the incumbent competitor's optimal response depends on its market dominance, with dominant brands (those with a market share of 50% or more) needing to increase spending and nondominant brands reducing spending.

Descriptive models of competitor response to new-product entry are typically based on econometric analyses of data from different markets. A simultaneous equation model by Robinson (1988) examines the effects of entry strategy, incumbent characteristics, and industry characteristics on incumbent marketing reactions in oligopolistic markets. Analysis using data from the Strategic Planning Institute on 115 new-product entries shows that incumbents do not react in the first year after entry and about half of them are passive in the second year after entry. The analysis, however, reveals that reactions in the second year after entry are more aggressive.

In another descriptive model, Gatignon, Anderson, and Helsen (1989) examine how established competitors react to a new-product entry in an over-the-counter gynecological product and in the airline industry. Their model focuses on the effectiveness of a current competitor's marketing mix instruments. The results show that incumbent firms retaliate with their more powerful marketing weapons and accommodate with less marketing instruments.

Using a game theoretic model that is both descriptive and normative, Shankar (1997) explains the pioneer's reactions and predicts its shift in marketing mix allocation upon new entry in a market. His competitive analysis involves study of equilibrium competitor reactions under

Nash and different leader-follower games and an empirical illustration of analytical results with empirical analysis of pharmaceutical data. The analysis shows that the type of competitive game and the anticipated impact of the late mover on the pioneer's margin and elasticities are two critical factors that significantly affect the pioneer's decisions, in addition to the pioneer's characteristics and the market conditions. The findings reveal that a follower (leader) role in a marketing mix variable, a static (growing) market, a decrease (increase) in own elasticity and margin, generally lead to accommodation (retaliation) in that variable. This model underlines the need to examine a combination of factors such as competitive structure, the impact of the late mover on the pioneer's elasticities and margins, competitors' marketing mix elasticities, and own elasticities to understand shift in competitors' marketing mix allocation.

Firms can also perform an analysis of the determinants of reaction time of competitors to a new-product introduction. A model by Bowman and Gatignon (1995) estimated on the profit impact of market strategies (PIMS) data identify significant predictors of response time. The findings show that response time is positively related to customer switching costs, the entering firm's market share, and new-product development time, but negatively related to market growth, the reacting firm's market share, and the rate of technological change. Another study of response times to easily imitated new products by MacMillan, McCaffery, and van Wijk (1985) shows that response time is strongly related to visibility, radicality, complexity, perceived potential, strategic attack, and organization misfit.

Firms can study the effectiveness of different response times to new-product entries. Gatignon, Roberts, and Fein (1997) find that faster reactions generally have a positive impact on the perceived success of the defending firm but too broad a reaction (in many marketing mix instruments) is less effective. Importantly, the results show that the ability of an incumbent to maintain its market position depends on industry characteristics and the magnitude of competitive threat from the new product.

Further insights into the magnitude and timing of incumbents' responses to competitive new-product entries are available. A delayed response may be an optimal or efficient strategy when the new product's quality is uncertain because an immediate reaction in the form of a lower price by the incumbent firm may cause consumers to believe that the new product's quality is high (Kalra, Rajiv, and Srinivasan, 1998). A good competitive analysis in this regard should treat customers as strategic agents.

Other factors that influence the speed and breadth of retaliation include rival product's innovativeness, market growth, market concentration, and competitor size. Kuester, Homburg, and Robertson (1999) show that innovativeness and firm size slow incumbent's reaction time, market growth expedites retaliation in the product mix, and concentrated markets induce firms to react less strongly on the product mix and exhibit slower reactions.

Analysis of competitor reactions in industrial markets reveals new insights into business-to-business competitive analysis. In an empirical study of 509 new industrial products launched in the United States, the United Kingdom, and the Netherlands, Debruyne *et al.* (2002) find that two-thirds of new product launches meet reactions by competitors after their launch, primarily in the form of price changes. The analysis further reveals that product assortment and promotional changes are less frequent; distribution policy modifications occur very rarely; competitors fail to respond to radical innovations and to new products targeted at niche markets; competitors react if a product can be assessed within an existing product category; and competitors react to new products with high communication spending and in high growth markets. Thus, competitive analysis in industrial markets should consider the characteristics of the new-product launch strategy and whether the new products are radical or incremental innovations.

Competitive analysis of responses should also consider signaling characteristics of the new entries. Three market signals, hostility, consequence, and commitment are important to consider (Heil and Walters, 1993). Research suggests that, in general, the hostility signal has the greatest impact on reaction strength

followed by the consequences signal and the commitment signal.

What are the factors that determine whether an incumbent will react to a new product announcement signal from a competitor, what are the variables that affect the aggressiveness of the incumbent's reaction, and what are the factors that influence whether the reaction will be in product or other marketing instruments? Robertson, Eliashberg, and Rymon (1995) address these questions based on survey data from the United States and the United Kingdom. Their results show that signal hostility is positively related to the occurrence of a reaction; an incumbent is more likely to respond when its fixed commitments in the product category is high and when the industry has high patent protection; and aggressive reactions are more likely under conditions of high signal credibility and in industries with high patent protection. Their findings further show that, in industries where patents are relevant, firms are less likely to make product changes and introductions; companies with high fixed commitments in the product category tend to react with other marketing mix elements, instruments, and hostile signals do not induce changes to product mix.

Competitors react to perceived market signals from a new product's launch decisions (broad targeting, penetration pricing, advertising intensity, and product advantage). Analysis by Hultink and Langerak (2002) on the effects of three perceived market signals on the strength and speed of competitive reaction shows that incumbents consider high advantage new products to be hostile and consequential and regard penetration pricing and intense advertising to be hostile, especially in fast-growing markets. Their results also reveal that broad targeting is not perceived to be hostile, especially not when used by entrants with an aggressive reputation and that perceived signals of hostility and commitment positively impact the strength of reaction while perceived consequence signal positively impacts the speed of reaction.

How do we analyze competitive effects of new-product introductions and deletions and proactive and reactive actions by competitor firms? Shankar (2006) analyzes actions and actions in product line, price, and distribution,

6 competitive analysis

which include both anticipation and reaction components of market leaders and followers. His results show that market leaders have higher product line elasticities than followers, and that unlike followers, leaders have greater reaction elasticities than anticipation elasticities. These findings are useful in predicting which competitors will react in what marketing mix instrument.

Competitive analysis involving new-product entries and competitor responses have been based primarily on their impact on sales and market share. However, it is important to analyze their effects on the profits and firm values of different competitors, including the introducing firm. What are the competitive entry strategies that ensure both sales and profit growth and firm value? What are the competitor response strategies that result in market growth, but improved market position and profitability for incumbents? We do not yet have good answers to these questions.

OTHER ISSUES IN COMPETITIVE ANALYSIS

Competitive analysis can be enriched by including three topics that are becoming increasingly important for firms in a growing competitive landscape. These topics are competitive benchmarking, convergence analysis, and cooptition.

Competitive analysis can be enhanced by including competitive benchmarking. Competitive benchmarking involves analysis of the focal brand, SBU, or firm relative to the strongest competitor(s) and is typically done for strategies such as product strategy, promotion strategy, marketing communication strategy, sales force strategy, distribution strategy, and pricing strategy. Competitive benchmarking is closely related to analysis of best practices.

Competitive analysis is complex in converging markets. Convergence is a process by which the boundaries across industries, businesses, markets, geographies, or customer experiences become blurred, creating new competitors for firms (Shankar, Ancarani, and Costabile, 2010). Convergence competition increases in an economic downturn, involving new technologies, modified customer needs, and unconventional competitors, and market rules. For example, Danone's Danacol, a cholesterol-

lowering yogurt, is a convergent offering, resulting from the comingling of the food and pharmaceutical industries. Danacol's competitor set includes players from both food and pharmaceutical industries. When a firm from one industry crosses over and enters a market in another industry, it creates a convergent offering. For example, Apple entered the cell phone handset industry through its iPhone, while remaining in the computing and music player industries. The convergent firm gains competitive advantage by being present in different industries with common technologies and sometimes, customers. Convergence can also be created when firms from different industries fulfill a customer need with different types of offerings. For example, Danone from the food industry offers a cholesterol-lowering yogurt, while Pfizer from the drug industry markets a cholesterol-reducing drug, Lipitor.

Competitive analysis will not be complete without a review of *cooptition* – the term used to describe the situation where competitors in one market cooperate in some other market(s) (Brandenburger and Nalebluff, 1996). Firms engaged in cooptition cooperate in those markets or situations where they believe that such cooperation will lead to favorable outcomes such as cost reduction, quality improvement, and profit increase. For example, Toyota and Peugeot, traditional competitors in many auto markets around the world, cooperated by sharing components costs for a new car they developed for the European market in 2005. A good competitive analysis could include assessment of cooptition opportunities and potential in different markets with different competitors. Such an analysis is typically done using game theoretic models.

CONCLUSION

Competitive analysis refers to the evaluation of strategies relating to a focal brand, product, SBU, or firm relative to current and potential competitors in its market or industry. Competitive analysis is undertaken before the formulation and development of positioning strategy, value propositions, and marketing mix strategies. It is also undertaken for a new brand or product, in particular, prior to its launch in a new market. Game theoretic models are useful tools

for competitive analysis. Competitive analysis in a new-product entry context involves a solid understanding of a framework that comprises the determinants of new-product entry strategy, its interrelationship with competitor response, and the drivers of competitor response. Competitive analysis can be enriched by including competitive benchmarking, convergence analysis, and competition analysis.

competitor analysis

Venkatesh Shankar

Competitor analysis refers to the strategic evaluation of the strengths and weaknesses of current and potential competitors for a focal brand in its market(s) or for a focal strategic business unit (SBU) or firm in their industry(ies). Competitor analysis can be done at the product-market level, the SBU level, or the firm level. The main purpose of competitor analysis is to develop business and marketing strategies that are based on sustainable competitive advantage. The dimensions of strengths and weaknesses include financial resources, human resources, core capabilities and competencies, order of entry advantage or disadvantage, manufacturing expertise, research and development (R&D) expertise, brand equity, distribution clout, pricing power, promotional capability, and execution ability. Each current and potential competitor is assessed on these dimensions and a profile of each competitor is developed. An overall assessment is made on who the key competitors are and what critical strengths and weaknesses they bring to bear on the market. Such an assessment helps brands and firms anticipate future competitor actions and reactions and exploit any weaknesses or gaps in the market or the industry. Thus, competitor analysis provides a critical input to the development of a firm's competitive marketing strategy.

At the firm and SBU levels, competitor analysis involves the assessment of all relevant firms in the relevant industries. When applied at the brand level, competitor analysis is useful in formulating brand-positioning strategy. Customer perceptions of each brand's strengths and weaknesses in a given product market provide the inputs for deriving a perceptual map for that market. Using this information and data on the location and size of customer preferences, a brand can develop its positioning strategy. Competitor analysis helps brands differentiate themselves from other brands.

A good competitor analysis should include assessments of both current and potential future competitors. Future competitors include marketers of substitute products and those with alternative technologies capable of satisfying customer needs in the relevant markets or

industries. Competitors are typically identified first in the core product market and then in the adjacent or peripheral product markets. The most direct or relevant competitors can be identified on the basis of an analysis of the market structure, which includes such considerations as similarity of served needs, substitutability, cross-price elasticity, switching costs, and perceptual positions. With the rapid global growth in the penetration of the Internet, the competitor sets for most brands and firms have broadened to include players from different product markets and countries. Furthermore, a firm's competitor in one market could be its collaborator in another market, in particular, in the hi-tech industry. A sound competitor analysis should incorporate the implications of such possibilities. The competitor set for any brand or business unit or firm is dynamic as new players enter its markets and existing players leave those markets. Therefore, competitor analysis is performed at intervals of a year or less.

Competitor analysis is a useful tool for deciding whether to launch a new product. By combining competitor analysis with an analysis of own strengths and weaknesses and of external opportunities and threats, firms can better decide whether to introduce a new product. Firms typically decide to launch products when their strengths relative to their competitors outweigh their relative weaknesses in markets where opportunities surmount threats.

The term, *competitor analysis*, is used interchangeably with another term, *competitive analysis*, although competitive analysis typically refers to the assessment of a business situation with a view to develop a sound business strategy or marketing strategy relative to competitors. Competitor analysis provides an important basis for the development of such a strategy. Competitor analysis is an essential element of any marketing plan. In a typical marketing plan, it is a part of situational analysis, which is followed by marketing objectives and marketing strategy.

customer analysis

Barry J. Babin and Eric G. Harris

Few would argue with the notion that customers hold a key to success for businesses in competitive industries. Customers are the subset of consumers who choose to interact meaningfully with a particular business entity. Businesses, therefore, are challenged to convert consumers into customers and once they have done so, to retain them as customers. Value is the key tool that businesses use to accomplish this feat. Thus, businesses need intelligence about consumers if they are to make reasoned strategic and tactical decisions; these decisions are all directed at value creation. Customer analysis, then, is the process of generating intelligence from information collected about consumers in the form of data. Eventually, managers make this intelligence actionable through informed business strategy and tactics.

Theory plays a large role in customer analysis. In particular, analysts need to know what needs to be studied and how to study it. The “what” needs to be studied question is addressed through the accumulated body of theory dealing with consumer behavior. This theory in itself is largely derived from other disciplines including psychology, social psychology, anthropology, and economics. The “how to” study question is addressed through the accumulated body of knowledge dealing with consumer research. In a very real way then, consumer theory is firmly rooted in the philosophy of science and the method of learning about consumers is structured around the scientific method. Not only does consumer research reveal ways to gather information about and from consumers but it also is increasingly focused on ways of analyzing this data. This analysis brings the data to life by converting raw information into intelligence.

The purpose of this article is to provide a basic overview of customer analysis. We offer a perspective to customer analysis based on two frameworks, one, a framework for understanding consumer value, the other, a framework for generating consumer intelligence. The article illustrates how research and analysis vary on the basis of the particular aspect of consumer behavior being studied. No encyclopedia of

marketing would be complete without insight into studying consumers and this article is intended to fill this role.

CUSTOMER VALUE

Any attempt to analyze consumer behavior must begin with recognition of the importance of value. Value is the sine qua non of consumer behavior. In fact, according to Peter Drucker, the marketing concept should be focused on the creation of value for consumers (Usley, Morgan, and Sheth, 2008). Furthermore, the American Marketing Association acknowledges the key role of value in its very definition of the field of marketing:

“Marketing is the activity, set of institutions, and processes for creating, communicating, delivering, and exchanging offerings that have value for customers, clients, partners, and society at large.” (AMA, 2007, [http://www.marketpower.com/About AMA/Pages/Definitionof Marketing.aspx](http://www.marketpower.com/About%20AMA/Pages/Definitionof%20Marketing.aspx)).

While there have been a number of conceptualizations offered in the literature regarding the value construct, most can be summed up in one simple definition; *value* represents a personal assessment of the net worth obtained from an activity (Babin and Harris, 2009). As such, value amounts to the gratification that one receives from consumption or the total net benefit of service received. Importantly, both actors in an exchange give and receive value. Marketers receive value when they obtain resources, most often financial resources, in exchange for benefits derived from using or enjoying a product offering. Consumers receive value after a purchase has taken place through the process of consumption. For consumers, then, a simplified way of viewing value is through a function that highlights what consumers give up and what they get from an exchange. This follows a traditional view of value as “what I get versus what I give” (Zeithaml, 1988). This function is illustrated in Figure 1.

Consumers typically get benefits such as quality, convenience, and emotions from their exchanges with marketers. Likewise, they give up resources such as time, effort, money, and energy. Although this is a rather simple way of

Figure 1 Consumer value.

illustrating the value concept, it does illustrate the important “give and get” components.

DIMENSIONALITY OF VALUE

An important issue with regard to consumer value is the dimensionality of the construct. Although the dimensionality of value has received scant research attention, one useful typology suggests that two main components of value help capture the construct *utilitarian value* and *hedonic value* (Babin, Darden, and Griffin, 1994). A consumer realizes the utilitarian value when he/she purchases a product that, when consumed, helps solve specific problems. For example, when a consumer buys something as mundane as a stapler, there is a specific problem that is to be solved. Attaching papers together creates greater organization and facilitates the user’s work. In this way, utilitarian value is thought of as a “means to an end” (Babin, Darden, and Griffin, 1994). In other words, by buying a stapler the consumer is able to solve a problem that is encountered frequently. The stapler, in and of itself, provides a solution to a common, tangible problem, though owning it provides no value. That is, until it is used, it is relatively useless.

Hedonic value is focused on the immediate gratification that results from some consumption activity (Babin and Harris, 2009). This value is associated with the act of consumption and the emotions that come along with it. Little hedonic value is obtained from the act of stapling pieces of paper together, however, a great deal of hedonic value is found in a visit to an amusement park, a sporting event, an art museum, or a fine dining establishment. Consuming fine champagne is a multisensory experience that epitomizes hedonic value, whereas utilitarian value is influenced by evaluation of consumption components such as convenience and efficiency. Hedonic value is driven by the emotions and feelings that emerge

during the act of consumption (Babin and James, 2010). One seldom goes to a theater production to be educated. Generally, the theater production is consumed primarily because the time invested as an audience member is gratifying immediately.

CONSUMER VALUE FRAMEWORK: THE “WHAT” OF CONSUMER ANALYSIS

As a general statement, then, customer analysis must begin with an appreciation of the importance of value, its dimensionality, its role in consumer behavior, as well as the myriad of variables that influence the construct. Some theoretical orientation is necessary to narrow down the range of potential phenomena that might be useful in explanations. One constructive framework for understanding the many variables that can influence the value derived from consumption is the “consumer value framework (CVF)” (Babin and Harris, 2009). This framework is illustrated in Figure 2. The framework addresses the “what” question of consumer analysis by providing a snapshot of important variables to consider in any consumer research effort.

Figure 2 indicates that numerous variables work to influence consumption-related behaviors, and ultimately, the value that consumers receive from products, services, and experiences. Internal influencers are derived directly from the field of psychology. Here, we find topics such as learning, perception, memory processes, consumer information processing, categorization, attitude, and personality. All of these concepts are crucial for studying consumer behavior. External influences, long recognized in the field of social psychology, include topics such as acculturation/enculturation, culture, reference groups, social class, and family influence. Situational influencers are also important to consider here. These include topics such as atmospherics, time pressure, and conditions.

The relationship between the marketer and the consumer also plays an important part in all of consumer behavior and analysis. Firms commonly focus on customer relationship management (CRM) techniques to ensure that long-lasting relationships exist between company and customer. Important topics here include customer satisfaction/dissatisfaction,

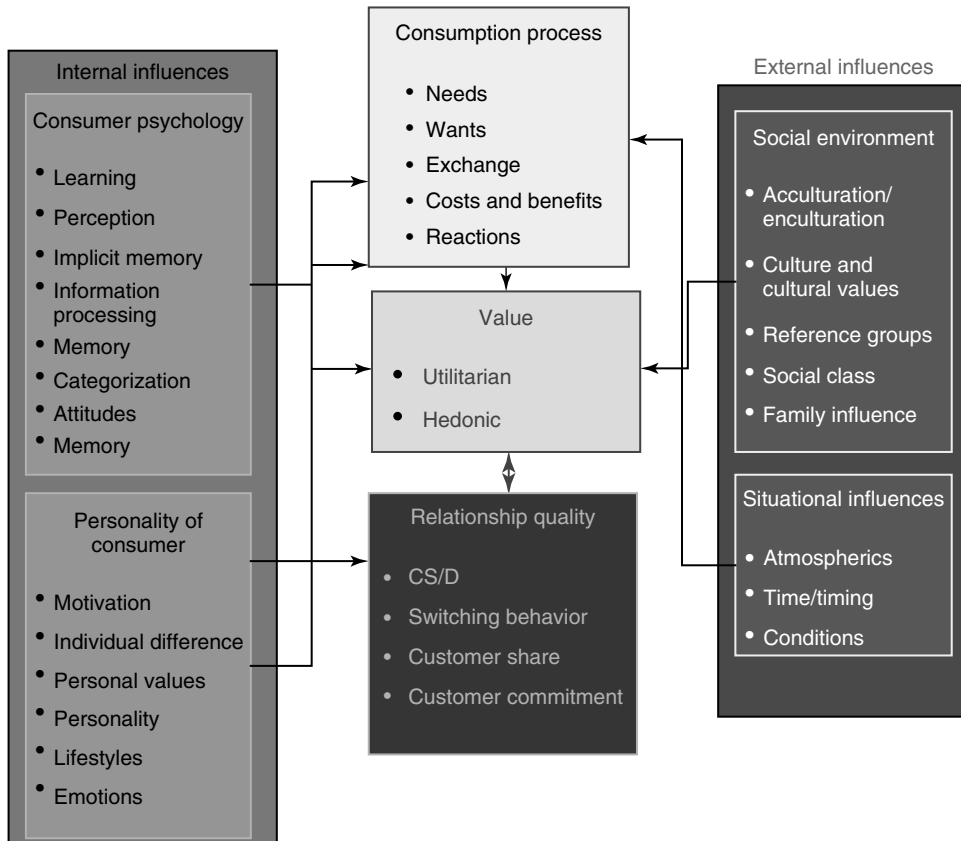

Figure 2 Consumer value framework (see Babin and Harris, 2009).

consumer switching behavior, customer “share,” and customer commitment.

It is important to emphasize that much research attention has been given to the customer satisfaction/dissatisfaction concept at the expense of customer value. As Babin and James 2010 discuss, however, a great deal is to be gained by focusing on customer value. In fact, many highly successful marketers (e.g., Walmart) have shown that delivering customer value is a major part of a successful marketing strategy. Of critical importance here is the realization that customer value drives customer loyalty in a way in which customer satisfaction does not.

CUSTOMER ANALYSIS IN PRACTICE

While the CVF provides an integrated view of the “what” to study in consumer analysis,

the question of “how” to perform consumer analysis is answered by following scientific research principles applied specifically to customer analysis (see Figure 3). Although the research process is not the primary focus of the current work, we can say that research follows a scientific process aimed at uncovering truths – in this case, truths about consumers (Zikmund and Babin, 2010). Customer analysis focuses on uncovering the myriad of factors that influence customer value. This process can occur in both applied and basic research settings, that is, customer analysis can be applied to very specific situations and/or problems (as when a company analyzes its customers in order to increase sales), or it can be applied by academicians who attempt to gain better understanding of consumer psychology and how it impacts buying decisions, and ultimately, value.

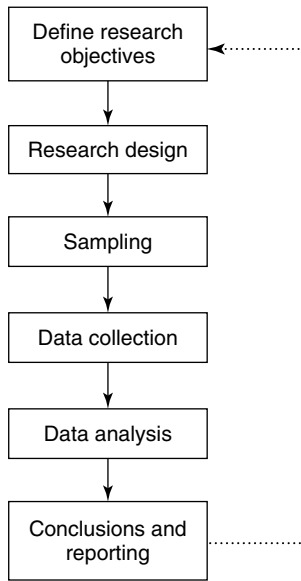

Figure 3 A framework for research aimed at customer analysis.

Customer analysis, therefore, involves research. As a result, it follows basic research principles and the basic steps of the scientific method: (i) defining the analysis objectives; (ii) planning an analysis research design; (iii) planning a sample; (iv) collecting data; (v) analyzing the data; and (vi) formulating conclusions. Although it is quite common that most marketing research efforts focus on relatively large samples, customer analysis is often applied to individual consumers. Of course, this is dependent upon the purpose of the research.

The three basic categories of consumer research designs are *exploratory*, *descriptive*, and *causal research*. *Exploratory research* is performed when the researcher knows very little about the particular subject matter or situation. The goal here is to simply gain an understanding of the consumer behavior phenomena with the expectation that more conclusive research is likely to follow. Popular techniques for exploratory research studies include pilot studies, case studies, and experience surveys. Interpretive research is often used as an exploratory research tool. An interpretive approach can involve ethnography or phenomenology. In either

case, the researcher takes on a more involved role in observing and/or interacting with research respondents. The data can take the form of interview text, a story completion, a collage, or other observational field notes. An interpretive researcher then derives meaning from this data and the meaning can be useful in establishing a potential explanation. *Descriptive research* is undertaken when the researcher has a basic idea of the subject matter and simply wants to describe the characteristics of people, situations, organizations, or environments. Surveys, secondary studies, and observation techniques are popular tools for descriptive research. Common statistical tools include cross-classification, independent sample *t*-tests, multiple regression, and factor analysis. *Causal research* is performed when the research has the purpose of establishing “cause and effect” relationships between variables. Experimental designs are popular tools for causal research. Experimental research often involves statistical analysis using some form of an analysis of variance (ANOVA) model. Experimental designs are particularly common in basic consumer research such as that published in the *Journal of Consumer Research*.

Customer analysis approaches. Customer analysis can be based on results from either *qualitative* or *quantitative* research. Qualitative approaches are often interpretive and focus heavily on researcher interpretation with little or no regard for numerical measurement of consumer phenomena, whereas quantitative research techniques rely heavily on numerical measurement of research observations. Qualitative techniques are often used with relatively small sample sizes. These approaches include techniques such as *phenomenology* (the interpretation of the lived experience), *ethnography* (a technique that requires the researcher to be immersed in the research context itself), and *focus groups* (unstructured interviews of a small group of consumers). Such techniques are said to be *researcher dependent* because they rely heavily on the interpretations of the observer. These techniques have gained in popularity among consumer researchers and are utilized regularly in customer analysis. In contrast, quantitative approaches involve techniques like

survey designs, experimentation, and statistical analysis. Quantitative approaches often use relatively large sample sizes. Regardless of the research design that is utilized, researchers must work to ensure that the results obtained are both valid and reliable. There are several techniques available for assessing the validity and reliability of customer analysis studies, though these techniques are beyond the scope of the current work. Qualitative approaches such as these are very commonly employed to develop explanations of the way customers might behave.

Data in customer analysis. There are many ways in which data can be collected for customer analysis. Survey methods generally require that respondents complete mail, e-mail, or door-to-door surveys. The survey procedure can sometimes require the use of a trained interviewer or research assistant who helps record consumer responses. Or, in some circumstances, respondents complete the surveys themselves. Data can also be collected by trained observers who simply observe consumer behavior. Yet another way of collecting data is by using some type of mechanical equipment such as video recorders or sophisticated psychological equipment such as *psychogalvanometers* or *voice-pitch analyzers*. We emphasize once again, however, that the focus of customer analysis is often on individual customer responses. As such, qualitative techniques such as depth interviews are extremely applicable. Customer data gathered using a qualitative approach lends itself more directly to interpretive scrutiny than to statistical analysis.

Data analysis. Data analysis is a critical phase of customer analysis. In this phase, the raw data that are collected in the study are transformed via some type of analytical technique into meaningful information. Some refer to this step as *data transformation*. The selection of analytic technique depends on the specific research design.

Qualitative or interpretative designs often require some type of categorization or theme generation. In this step, the researcher attempts to categorize data in either existing or “emergent” categories. In doing so, the researcher must consider the context from which responses

are taken. For example, a researcher may focus on the meanings that consumers attach to possessions that are handed down from generation to generation. To do so, they would rely heavily on interviews and life stories of family members in order to gain an understanding of the meaning of such possessions. This would take place in the absence of consumer surveys or other quantitative approaches. A great deal of training is necessary for a researcher to effectively interpret qualitative data.

There are numerous quantitative analysis techniques that are available to the consumer researcher. As mentioned earlier, survey and experimental designs lend themselves well to data analysis tools such as *regression analysis*, *ANOVA*, *correlation analysis*, and *t-tests*. However, researchers must often utilize more sophisticated multivariate data analysis techniques such as *cluster analysis*, *discriminant analysis*, *canonical correlation*, *conjoint analysis*, and *structural equations model (SEM)*. Although the details of these techniques are beyond the scope of the current article, it is worth noting that these techniques are used commonly in consumer analysis. Several software packages are available, including *SPSS*, *SAS*, *LISREL*, *Mplus*, and *AMOS*. Quantitative techniques generally require a great deal of training in specific statistical theory. Regardless of the complexity of the technique, however, the goal of most quantitative research remains the same: to obtain information from the sample data that can be inferred to the population of interest.

Drawing conclusions. Transforming data into usable information is an important part of the customer analysis process. Regardless of the complexity (or simplicity) of the study, useful information is critical. In fact, communicating research results is one of the most important phases of the entire research process (Zikmund and Babin, 2010). Of course, the audience of the research study must be considered. For applied research studies, the audience generally consists of managers who are seeking to make business decisions that are based on the information

Table 1 Examples of research aimed at consumer analysis.

| <i>Area of CB Involved</i> | <i>Research Question</i> | <i>Research Design</i> | <i>Research Description</i> | <i>Results</i> | <i>Reference Citation</i> |
|---|---|------------------------|--|--|-------------------------------|
| Internal influences – motivation value | What is the nature of consumer motivation in pet consumption? | Exploratory | Interpretive research involving ethnography of show dog owners. | Specific insights into motivations of dog-related marketing. | Bettany and Daly (2008) |
| Internal influences – personality of consumer Consumption process | What are the lifestyle characteristics distinguishing heavy online shoppers versus online shopping avoiders? | Descriptive | A survey using a probability sample representing US consumers. | Online shoppers are relatively young, wealthy, and live a lifestyle highly oriented around the Internet. | Swinyard and Smith (2003) |
| External influences – family influence | How does the degree of family communication influence the transmission of brand attitudes from parents to children? | Descriptive | A survey of elementary school children in Taiwan. | Brand attitudes of Taiwanese children are influenced by parents and these effects are influenced by social and concept orientations. | Hsieh, Chiu, and Lin (2006) |
| External influences – culture and situation value | How do Asian consumers from different countries react to different levels of service performance? | Causal | A lab experiment manipulating characteristics of the service environment (atmosphere). | Chinese subjects display greater variance in satisfaction than do Korean or Japanese subjects. | Ueltschy <i>et al.</i> (2009) |
| External influences – social class | What is the role of disempowerment as a central phenomenon of social class? | Exploratory | A series of in-depth interviews of workers in Sydney, Australia. | Relative empowerment contributes to distinctive financial approaches to decision making | Henry (2005) |
| Situational influences on decision making | How do repeated incident exposures to features of the everyday environment influence product evaluation and choice? | Causal | A combination of quasi and lab experiments utilizing samples of US consumers. | The prevalence of perceptually and conceptually related stimuli can shape product judgment and decision making | Berger and Fitzsimons (2008) |

Table 1 (continued).

| Area of CB Involved | Research Question | Research Design | Research Description | Results | Reference Citation |
|--|---|-----------------|--|--|---|
| Influence of atmospherics on decision making | When and how does the meaning of music influence perceptions of an advertised product? | Causal | Lab experiments manipulating need for cognition and processing intensity, message format, and type of music. | Nonintensive processors are insensitive to the meaning of music but intensive processors base perceptions on meaning. | Zhu and Meyers-Levy (2005) |
| Postconsumption processes | What is the relationship between hedonic and utilitarian benefits and postconsumption feelings of delight and satisfaction? | Causal | A lab experiment manipulating product design benefits and consumption experience. | A product that meets or exceeds utilitarian expectations evokes satisfaction, whereas a product that meets or exceeds hedonic expectations evokes delight. | Chitturi, Raghunathan, and Mahajan (2008) |
| Decision making and value | What are elements that translate into value from the purchase of high-tech products by business customers? | Exploratory | Interpretive approach based on data from in-depth interviews of business customers. | Business perspective on what are important elements varies on the basis of the role one plays in the decision process. | Lindgreen <i>et al.</i> (2009) |
| Consumer cognition and decision making | How does the inclusion of functional health claims on food products alter perceptions of value (i.e., choice)? | Causal | A lab experiment manipulating product labeling – specifically functional health claims. | Health conscious consumers are most likely to choose something with a functional claim – even when presented with conflicting information. | Naylor, Droms, and Haws (2009) |

provided. For basic research studies, the audience largely consists of consumer researchers who are seeking to learn more about consumer behavior so that they can advance consumer research theory.

EXAMPLE APPLICATIONS FOR CUSTOMER ANALYSIS

Table 1 provides a brief overview of published examples of the types of analytical approaches

that have been described. Each study involves drawing generalizations about consumers with varying degrees of certainty. Some areas of consumer behavior lend themselves better to certain types of research designs. Studies of consumer motivation sometimes prove difficult for survey research or even causal research. Manipulating motivation can be troublesome. Thus, interpretive research is often employed. These techniques are often aimed at relatively small samples of consumers. Bettany and Daly (2008) employ this approach in studying consumer motivations for pet-related consumption activities. In contrast, studies involving individual difference characteristics like demographics, personality, or lifestyle, lend themselves very well to descriptive research employing consumer surveys, often with large sample sizes. The Swinyard and Smith (2003) study analyzes characteristics of online shoppers and typifies this approach. Finally, studies involving consumer perception, atmospherics, and decision processes lend themselves well to experimental designs. This is because the characteristics of different marketing stimuli such as advertising copy or even physical elements like odor can be manipulated easily in laboratory environments (see Ueltschy *et al.*, 2009). Basic (or academic) research analyzing results from studies effectively matching the analytical approach to the research question about consumers has contributed and will continue to contribute to the development of consumer behavior theory and to effective analysis of customers by practitioners.

Consumer analysts also recognize that the term customer does not always involve an individual family member or even a household. Businesses are customers too and the contribution of business-to-business spending to the GDP of most developed nations is approximately equal to that of business-to-consumer spending. Thus, a significant amount of customer analysis addresses business consumers. Lindgreen *et al.* (2009), for example, provide a typical business customer analysis, in this case, employing a qualitative approach, in which they explore the key elements that make a high-tech product more valuable in the eyes of the business customer. Likewise, customer research is not always motivated by a specific marketing problem for a

business. The government is also interested in customer analysis. Each public policy decision that involves a restriction in the marketplace should be informed by research. Food product labeling is regulated in every developed country. Thus, a significant amount of consumer research addresses the ways consumers react to different types of product claims and different ways to present health-related claims. Researchers, for example, analyze the way customers react to claims that a product provides some health function such as aiding digestion (Naylor, Droms, and Haws, 2009). In this case, a causal design allows analysis aimed at more informed government decisions on labeling.

No matter how the research is generated, customer analysis provides critical information for theory development, businesses, and governments. Without valid analysis, decision makers are left to make decisions based solely on intuition, politics, or pure guess work. For instance, decisions about what consumer segments to appeal to involve analysis matching the personality of a consumer to the personality of a brand; decisions about how to communicate nutrition information appropriately involve analysis of psychological processes; and decisions about environmental design involve analysis of key situational and cultural variables. Intelligence is the key to reducing the risk of decision making. In the end, valuable outcomes for consumers can best be delivered when decision makers have some idea of the processes by which value can be created.

thinking deeper about customer experience

Jerry Olson and Gerald Zaltman

In recent years, marketers have become aware of the importance of customer experience (Carbone, 2004). Service companies such as theme parks, restaurants, and airlines quickly recognized that an emotional experience is the primary benefit they provide. Somewhat belatedly, product-oriented companies realized that tangible products also provide customers with important experiences.

We propose that a person's thoughts and feelings about an event are central to customer experience. Table 1 shows that marketers have not always treated customer experience in that way.

In more than a few cases, observations of "what happened" have been treated as experience. Marketers can learn "what happened" through secondary sources (How many people repurchased brand A within six weeks?) or ethnographic observation (How many brands do consumers examine in the cereal aisle?) (see DESCRIPTIVE RESEARCH; PERSONAL OBSERVATION). Although such descriptions can be useful, they are not true experience. Rather, experience resides in a customer's interpretation of "what happened." When marketers do not know how customers understand "what happened," they must imagine the meanings and feelings that constitute experience. That intuition is often wrong and can lead to costly mistakes.

Identifying customers' feelings of "what happened" as an event occurs does reflect true experience, but measuring such phenomenological reactions is difficult. Consider how we could measure customers' real-time thoughts and feelings during the course of a grocery shopping trip. We are able to capture physiological reactions (e.g., galvanic skin response, heart rate, or perhaps eye fixations) for relatively simple behaviors such as reactions to an ad. However, physiological measures do not reveal customers' cognitive and emotional interpretations. Moreover, we know that quite different feelings can produce similar physiological signatures. For more complex experiences such as a day at a theme park, it is easier to obtain

customers' self-reported thoughts and feelings immediately following the behaviors of interest. However, these "direct" measures can access only phenomenological reactions of which the customer is consciously aware, and we know that significant aspects of customers' experience will be unconscious.

Perhaps the best indicators of customers' experience access memories of "what happened," since memories reflect prior interpretations by the customer (see CONSUMER MEMORY PROCESSES). Memory-based measures are influenced by many factors, including the amount of time since "what happened," the number of prior recalls of "what happened," and the type of questioning. Direct requests to remember "what happened" are likely to yield relatively shallow accounts of experience. To identify the deeper aspects of experience, including customers' mostly unconscious interpretations of "what happened," we need more sophisticated measures.

The Zaltman Metaphor Elicitation Technique (ZMET) uses metaphor to help customers access and describe the deeper, often unconscious meanings associated with an experience (Zaltman, 2003). In a ZMET study, customers are asked to find pictures (sometimes, objects) that represent their thoughts and feelings about an experience of interest. Each picture is a metaphor for some relevant aspect of the customer's experience; often an unconscious meaning, emotion, or orientation that cannot be accessed by direct questioning. In projecting their thoughts and feelings onto the pictures, customers tell stories that reveal the interpreted meanings of their experience, often in rich detail (see PROJECTIVE TECHNIQUES).

For example, consider a ZMET study in which we asked theatergoers to find images that express their Broadway theater experience. The stories these customers told revealed the conscious and unconscious feelings and meanings of their remembered Broadway experiences. A key unconscious metaphor was Container, indicated by customers' stories about the various "places" where they experienced Broadway theater. As customers moved in and out of the various "Containers of Broadway meaning," they experienced different thoughts and emotions. For instance, theatergoers described

Table 1 Three types or levels of experience.

| <i>Type of Experience</i> | <i>Interpretation</i> | <i>Possible Measures</i> | <i>Example</i> |
|-----------------------------|---|---|---|
| Observed behavior | What happened | An external observer's account of customers' behaviors in a situation as captured by ethnography or video recording. | Susan waited in line at Starbucks for 3.45 minutes. |
| Phenomenological experience | The feeling of "what happened," as it occurred | Physiological measures taken during the situation; or immediate self-reported feelings. | Susan felt only slightly frustrated by her wait as she was distracted by the product displays around her. |
| Remembered experience | The meaning of what happened, as stored in memory | Retrospective interpretation of one's behavior in a situation. This process blends three things: the memory of what happened, the memory of the feelings that were experienced, and the currently activated mental frame. | Over lunch, Susan told a friend about her recent visit to Starbucks. Her feelings about waiting in line to be served were not a relevant aspect of her experience; rather she described two products that caught her interest during that time. |

feelings of excitement and anticipation as they entered the hustle and bustle of the Broadway area in New York. When customers entered the "different world" of the theater building, they imagined theater customers of bygone days and felt a connection with them. The play also was framed as a "container" into which theatergoers became immersed. Often, they became "lost in" the story line as they "explored" how the play is relevant to issues in their own lives. After leaving the theater, some customers entered into extensive discussions with friends about their feelings and interpretations, the final "container" of their Broadway theater experience.

We propose that marketers develop and apply measurement tools like ZMET that

can uncover the deep and rich aspects of customer experience. Gaining a deeper understanding of how customers think and feel about "what happened" will help marketers develop more effective ways to improve the experiences of their customers (see CUSTOMER SATISFACTION/DISSATISFACTION; CUSTOMER-SATISFACTION RESEARCH).

customer lifetime value (CLV)

Katherine N. Lemon and Loren J. Lemon

Customer lifetime value (CLV) is defined as the net profit from a customer (customer margin less the costs of acquiring and serving the customer) over the lifetime of the customer's relationship with the firm, discounted to the present. One of the key objectives of CLV is to assist in the estimation of how much a customer/customer segment (new or existing) is worth to a firm over the lifetime of the customer's relationship with the firm in current terms (e.g., today's dollars). While the terminology may vary from model to model, the essential elements of CLV estimation consist of the following:

- Acquisition cost
- Time interval
- Net profit
- Retention rate
- Discount rate

To understand CLV, it is important to understand the definitions of each element of CLV.

First, acquisition cost is equal to the costs the firm incurs in first securing the customer less any revenues derived by the firm from the customer at the time of acquisition. Second, time interval is the time periods (usually years) and overall time horizon selected for a given CLV estimation. While this may be infinite, usually a specified interval is selected based on the firm's general "life expectancy" of its relationships with the customer(s) being analyzed. An appropriate time interval for most CLV estimates is three to five years. Third, net profit is the expected future profits to be derived from the customer(s) being analyzed for the selected time interval. This is often considered to be the "net margin" from such transactions or the recurring revenue derived from the customer less any recurring costs in servicing the customer. These costs should ideally be directly associated with the customer. Fourth, retention rate is the expected probability that the firm will retain the customer as a customer during the selected time interval. Finally, discount rate is the rate used in calculating the "net present

value" of the future profits derived from the customer. The usual reference point in selecting the discount rate is the firm's weighted average cost of capital.

The basic model of CLV is presented below. CLV is typically expressed as the following mathematical formula in Equation 1:

$$\sum_{t=0}^T m \frac{r^t}{(1+d)^t} - AC \quad (1)$$

where

AC = Acquisition costs,

t = Time interval,

d = Discount rate,

m = Net profit,

r = Retention rate.

When the following specific assumptions are satisfied, the equation simplifies to Equation 2 below:

- recurring net profit (m) is constant over the life of the customer,
- retention rate (r) is constant over the life of the customer,
- discount rate (d) is constant over the life of the customer.

$$CLV = \frac{m}{1-r+d} - AC \quad (2)$$

It is important to note that CLV estimations can be made for a specific customer, specific customer segment, or a generalized calculation based on the firm's generalized experience for its customers. For decisions based upon CLV to be actionable, the customer segment estimated should be as homogeneous as possible. CLV is useful in assisting a firm in making a determination of whether any new initiatives by the firm are worthwhile (Berger and Nasr, 1998). For example, initiatives focusing on acquiring new customers can be evaluated to determine whether the costs of such new initiatives may be worth it given the potential expected future profits from such customers

2 customer lifetime value (CLV)

(see CUSTOMER RELATIONSHIP MANAGEMENT). Initiatives focusing on current customer (either to increase the revenues from existing customer or improving the retention rate for such customers) can be evaluated by first estimating the CLV for such customers prior to the initiative and then reestimating the expected CLV with the new initiatives.

CLV can also be used to determine which customer segments to focus on, which customers may not be worth retaining, and where sales and marketing efforts and other firm resources may best be deployed (see CUSTOMER EQUITY; CUSTOMER ANALYSIS) (Rust, Lemon, and Zeithaml, 2004). New and different applications of CLV analysis are constantly being developed (Fader, Hardie, and Lee, 2005; Jain and Singh, 2002).

There are some important caveats related to the use of CLV. At its best, it can be an accurate estimation of the future profitability of the customer examined but it is simply an estimate. CLV is highly dependent on the quality and accuracy of the data utilized. Depending on the complexity and sophistication of the CLV model and formulation used, the resulting estimate may not fully account for the very dynamic nature of the firm/customer relationship (Gupta *et al.*, 2006). In addition, except to the degree it is

accurately reflected in the customer retention rate, CLV does not account for the action of competitors. Finally, since not all customers are the same, an aggregation bias can occur, especially when a generalized approach is used in the CLV estimation as there could be substantial differences in retention rates, servicing costs, and the amounts and rates of customer transactions.

customer relationship management

V. Kumar

INTRODUCTION

A customer pulls into Harrah's Caesar's Palace in Las Vegas. A cheerful valet greets her by name and escorts her into the game room, circumventing the crowded lobby. Soon, a designated host approaches her and ensures that the service she is receiving matches her expectations. After her gaming session, she is escorted into the restaurant to her preferred table with her favorite wine waiting for her. This superior customer service is an instance of Harrah's building individual relationships with their high-value customers as a means to enjoy their continued patronage. Considering the satisfaction for customers and the subsequent repeat business it would generate for Harrah's, it is a win-win situation for both the company and the customers, and one that often leads to positive word of mouth and referrals for the company. This technique of developing a one-to-one relationship with customers is called *customer relationship management (CRM)*. While the example above illustrates the customer experience (see THINKING DEEPER ABOUT CUSTOMER EXPERIENCE) in a business-to-consumer (B2C) setting, appropriate measures can be adopted to manage relationships with vendors in a business-to-business (B2B) setting.

WHAT IS CRM?

The above example illustrates the power of database marketing (see DATABASE MINING AND MARKETING) and how it can be harnessed to identify and analyze customer segments for valuable information that can be used to increase the impact of marketing campaigns for companies. Further, with advancements in technology, it is now possible to capture customer data and interact with the customers simultaneously, as demonstrated by Harrah's. Therefore, CRM extends the concept of database marketing to a customer level in order to develop profitable company-to-customer relationships. The concept of CRM can then be used to create strategies for interacting with each customer.

Examples of such strategies include developing better relationships with profitable customers, locating and enticing new customers that will be profitable, and finding appropriate strategies for unprofitable customers, among others.

With this as the background, we can now see CRM from a business strategy perspective. By adopting such an approach, companies can gain long-term competitive advantage by optimally delivering value and satisfaction (see CUSTOMER SATISFACTION/DISSATISFACTION) to the customer and extract business value from the exchange. Kumar and Reinartz (2006) define CRM as follows:

CRM is the strategic process of selecting the customers a firm can most profitably serve and of shaping the interactions between a company and these customers. The goal is to optimize the current and future value of the customers for the company.

The key components of this definition include the following:

- *Strategic process*: This means that CRM activities are initiated and managed starting from the top of the organization. CRM does not belong to any single department but needs contributions and reinforcements from all corporate functions. Furthermore, CRM is a continuing *process* that cannot be handled as just another software implementation project. It must be viewed as a continuous effort with the goal of the company becoming more customer focused.
- *Selection*: When the economic value of a customer is the basis for resource allocation, it is logical that firms focus on their most profitable or potentially profitable customers first. This is not about denying services to certain customers but about recognizing that there is a fit between a firm's offering and a segment's desires, behavior, and characteristics.
- *Interactions*: This means that the relationship between the customer and firm takes the form of an interactive dialogue. Information and goods are exchanged and, most importantly, the exchange evolves as a function of past exchanges. This is very different

2 customer relationship management

from the view that firms sell one-off products and services to the customer (see SERVICES MARKETING STRATEGY).

- *Customers:* Depending on the industry and company, a customer can be an individual account, one or several segments within a market, or an entire market. Also, customers include not only end users but also intermediaries, like distributors, retailers, and so on.
- *Current and future value of the customer:* (see CUSTOMER SOLUTIONS) This means that firms are moving away from extracting their profit from single transactions to maximizing profits over a series of transactions. Thus, firms are starting to maximize CUSTOMER EQUITY – that is, the value of all their customer relationships to them. In this process, traditional measures such as market share are increasingly being replaced with new measures such as customer lifetime value (CLV).

CRM also involves automating and enhancing the customer-centric business processes of sales, marketing, and service. It not only deals with automating these processes but also focuses on ensuring that the front office applications improve CUSTOMER SATISFACTION, resulting in increased customer loyalty (see MARKETING METRICS) that directly affects the company's bottom line.

LOYALTY PROGRAMS

Companies have long used loyalty programs in an effort to assess the current and future value of customers. A loyalty program is a marketing process that generates rewards to customers on the basis of their repeat purchases. Consumers who enter a loyalty program choose to focus more of their buying with a particular company, thereby forgoing the free choice they had otherwise. In exchange for concentrating their purchases with the company, they accumulate assets (e.g., "points") that are exchanged for products and services, typically associated with the focal firm.

All successful loyalty programs have a unified objective and stress on an important aspect in customer management (CM) – it is cheaper to market to existing customers than to acquire

new ones. Considering the achievements of all loyalty programs thus far, we can summarize the key objectives of loyalty programs as follows:

- *Building true loyalty:* This refers to a greater commitment to the product or organization through the building of true loyalty, both attitudinal and behavioral. Attitudinal loyalty refers to the perceptions and attitudes that a customer has toward a particular product or service. Behavioral loyalty, on the other hand, refers to the observed action that the customers have demonstrated toward a particular product or service. This objective is also not easy to achieve because consumers can be fickle and economic benefits are important to them. Hence, building true loyalty is the goal of many loyalty programs.
- *Efficiency profits:* This refers to the comparison of profit consequences with and without loyalty programs to determine where the biggest gain is obtained in terms of return on investment (ROI) or profit. Therefore, the goal of cultivating profitable loyalty is an important objective.
- *Effectiveness profits:* These are long-term profit consequences realized through better knowledge of customer preferences over time. This goal ensures that profitable loyalty created is sustainable over the long term in generating value for customers.
- *Value alignment:* Finally, building true loyalty and cultivating profitable loyalty should align the cost of serving a particular customer with the value he or she brings to the firm. This ultimate goal enables a firm to serve its customers in the best manner possible.

However, one has to keep in mind that not all of these goals may be pursued by the loyalty programs. It is possible for loyalty programs to concentrate on certain goals alone. Further, companies have to measure and manage customer loyalty in order to develop longerlasting customer relationships.

METRICS TO MEASURE AND MANAGE CUSTOMER LOYALTY

Traditionally, various metrics (see MARKETING METRICS) have been used to measure and

manage customer loyalty that are anticipated to be reasonable indicators of actual customer value. These metrics help firms prioritize their customers in a manner that allows a higher proportion of resources to be assigned to the customers who are expected to generate greater profits in the future. The following are some of the popular metrics used:

- *Recency, frequency, and monetary value (RFM)*: Recency refers to how long it has been since a customer last placed an order with the company, frequency refers to how often a customer orders from the company in a certain defined period and monetary value denotes the amount that a customer spends on an average transaction. The higher the computed score, the more profitable the customer is likely to be, in the future.
- *Past customer value (PCV)*: In this model, the value of a customer is determined on the basis of the total contribution (toward profits) provided by the customer in the past. Since products/services are bought at different points in time during the customer's life-time, all transactions are adjusted for the time value of money.
- *Share of wallet (SOW)*: This refers to the proportion of category value accounted for by a focal brand or a focal firm within its base of buyers. It can be measured at the individual customer level or at an aggregate level.

The metrics discussed above score customers on the basis of their past purchase behavior and rank order customers from best to worst. However, research has shown that these traditional metrics are poorly correlated with future profitability. Therefore, we need a forward-looking metric that overcomes these limitations and helps firms accurately measure and manage customers profitably.

NEED FOR A FORWARD-LOOKING METRIC

We have found a solution to this problem in the CLV metric (*see* CUSTOMER LIFETIME VALUE (CLV)). Unlike other traditional measures that include only past contributions to profit, the merit of CLV rests on the fact that it is a forward-looking metric. The conceptual approach to compute CLV is illustrated in Figure 1.

The CLV metric can be computed using three main components: (i) contribution margin, (ii) marketing cost, and (iii) probability of purchase in a given time period (Reinartz and Kumar, 2003). Each of these models will have a set of drivers/predictors. These three models are estimated simultaneously. By applying this approach, managers can estimate the CLV for each customer in the firm. The calculation of CLV for all customers helps the firms to rank order customers on the basis of their contribution to the firm's profits. Such an analysis would help the firm to treat each customer differently on the basis of his or her contribution, rather than treating all the customers in a similar fashion.

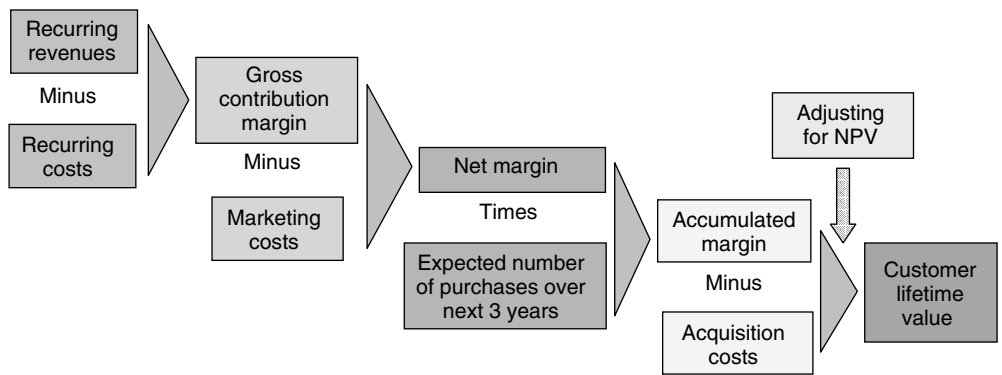

Figure 1 Approach to CLV measurement.

4 customer relationship management

CLV assists marketers to adopt appropriate marketing activities today in order to increase future profitability. In addition, the computation can also be used to include prospects, not just current customers as used by the recency, frequency, and monetary value (RFM), share of wallet (SOW), and past customer value (PCV) metrics. Further, CLV is the only metric that incorporates into one, all the elements of revenue, expense, and customer behavior that drive profitability. This metric also manages to score over other metrics by adopting a customer-centric approach instead of a product-centric one, as the driver of profitability (Kumar, 2007).

One of the key outcomes in using CLV as a metric is in achieving convergence between marketing actions (e.g., contacts across various channels) and CRM. When managers have computed the CLV of their customers, they must look forward to maximize it in order to reap the benefits of the metric. The following section discusses the various strategies that firms can use to maximize CLV.

STRATEGIES TO DEVELOP PROFITABLE CUSTOMER RELATIONSHIPS

Using a powerful metric such as CLV, firms can address marketing issues with greater confidence. This metric will also help companies to develop important CRM strategies that will help them develop profitable relationships with their customers. Figure 2 illustrates the strategies, known as the *Wheel of Fortune* (Kumar, 2008).

Implementing these strategies is a cyclical process. The knowledge acquired in implementing these strategies should be used as the basis for deciding which customers to pursue in the future and how to select the most profitable set of customers. A brief synopsis of all the strategies is provided in this section.

Customer selection.

The strategy. The objective of customer selection is to detect and target customers/distributors on the basis of their value potential as opposed to other traditional metrics like RFM, PCV, and SOW. This strategy is applied when firms want to target individual customers

or groups of customers. The reason for targeting these customers can be manifold, for example, for sending out a promotion or for inviting them to a special event. Finding the right targets for marketing resource allocation is at the heart of any CRM strategy. Smart targeting actions add value to the firm as well as to the customer.

Need for the strategy. First, the marketing budget of a firm is limited, and managers have to make choices as to where and on whom they should spend the limited resources available to them. Second, not all customers are equally profitable. An overwhelming share of profits is generated by a small percentage of customers. This necessitates targeting those customers with high profitability, and this is the basis of the customer selection strategy. Traditionally, firms rank order customers based on their profits and prioritize their resources based on this ranking. Among the metrics discussed in the previous section, the forward-looking CLV metric is the most successful in predicting future customer profits.

Benefits of this strategy. The performance of the traditional metrics (RFM, PCV, and SOW) versus the CLV metric in customer selection has been compared numerous times with CLV always offering higher levels of profitability. For example, Venkatesan and Kumar (2004) found that the net value generated by the customers who were selected based on the CLV score is about 45% greater than that generated through customers selected through other traditional metrics. This shows that using CLV to select customers is far more effective than using the traditional metrics. These findings provide substantial support for the usefulness of CLV as a metric for customer scoring and customer selection.

Managing loyalty and profitability simultaneously.

The strategy. Companies should manage customers who are *profitably* loyal and not just loyal. This is based on the finding by Reinartz and Kumar (2002) that not all loyal customers are necessarily profitable, and not all profitable customers are necessarily loyal. By managing loyalty and profitability simultaneously, this

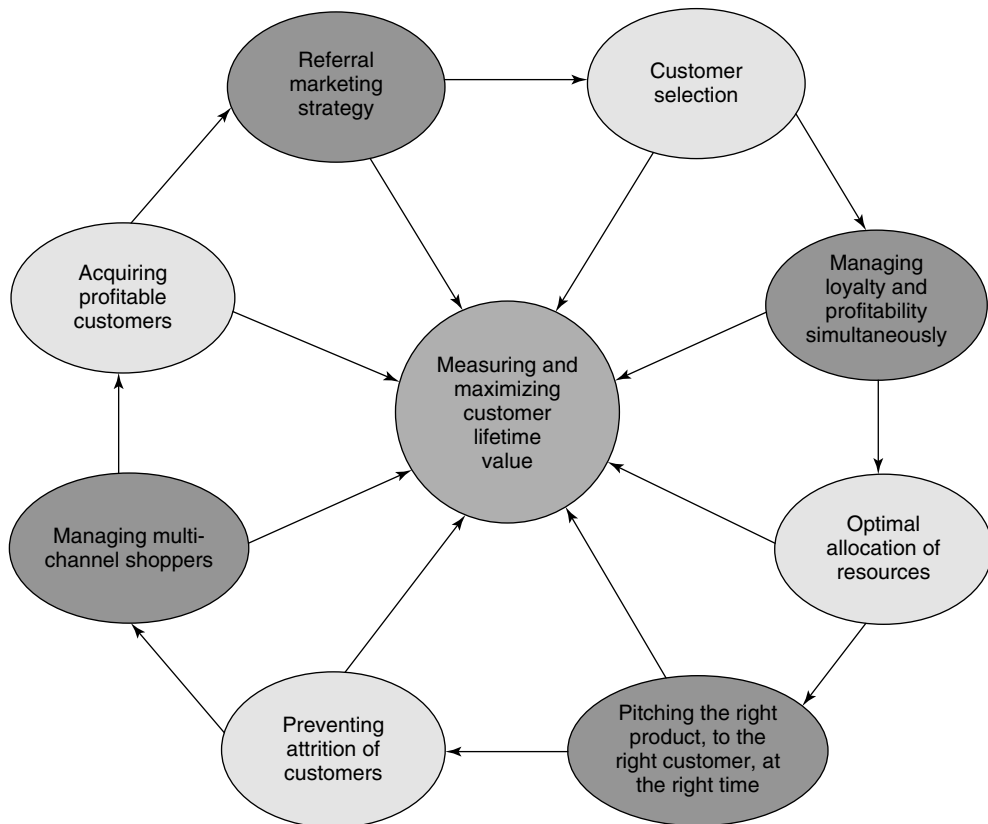

Figure 2 The Wheel of Fortune. *Source:* Adapted and updated from Kumar, V. (2008), *Managing Customers for Profits*, Upper Saddle River, NJ: Wharton School Publishing.

strategy clarifies the relationship between loyalty and profitability and provides managers with the required framework to manage loyalty and profitability at the same time. Implementation of this strategy calls for segmenting customers on the basis of their loyalty and profitability to the firm. There are several measures of loyalty and profitability that can be used for this purpose. Customers are segmented into cells on the basis of their loyalty and profitability levels. The four cells are as follows:

- *Cell 1 – Strangers (low profitable and short-term customers):* This set of customers is not loyal to the firm and bring in little to no profits to the company. These customers have very little fit between the company's offerings, and have very little

profit potential. They have to be identified very early on, and any investment toward building a relationship with them should be avoided. Profits should be made from every transaction with these customers.

- *Cell 2 – Butterflies (highly profitable and short-term customers):* These are transient customers who can be very profitable, but often do not exhibit traditional behavioral loyalty. These customers tend to buy a lot in a short time period and then move on to new firms after making those transactions. These customers avoid building a long-term relationship with any single firm. Therefore, firms should adopt a more prudent approach in managing them—enjoy their profits while it lasts and stop investing in them at the right moment when they switch.

6 customer relationship management

- *Cell 3 – True friends (high profitable and long-term customers)*: These customers are both loyal and profitable, and buy steadily and regularly (not too intensively) over time. True Friends are generally satisfied with existing arrangements with the firm, and are usually comfortable engaging with the firm's processes. Care should be taken in building relationships with these True Friends, since these customers have the highest potential to bring long-term profitability.
- *Cell 4 – Barnacles (low profitable and long-term customers)*: These customers, if managed unwisely, could prove to be a severe drain on the company's resources. The size and volume of the transactions made by these customers are too low to justify the cost incurred in marketing and maintaining their accounts. The primary step in managing these customers is to evaluate the size and share of their wallet. If the SOW is found to be low, specific up-selling and cross-selling can be done to extract profitability. However, if the size of wallet is small, then, strict cost control measures can reduce the loss for the firm.

Need for the strategy. This segmentation strategy is helpful for firms in building an effective loyalty program – one that is aimed at maximizing profitability for the firm. With the four segments as the base, firms can aim to (i) build and enhance behavioral loyalty by focusing on purchase behavior of individual customers and their respective contributions to firm profit, (ii) cultivate attitudinal loyalty by studying customers' attitudes toward the firm through customer feedback and focus groups, and (iii) link loyalty to profitability by using the CLV metric, and ensure a successful loyalty program. This would help companies to identify the high-value customers and spend the limited marketing resources on them.

Benefits of the strategy. All customers are not equally profitable. This should be remembered when putting a loyalty program in place. This strategy would help the firm reward customers depending on their level of profitability, such as a two-tiered loyalty

program (Kumar and Shah, 2004). The tier-1 rewards are aimed at all customers based on their current and past purchase behavior. This tier-1 reward is a simple explicit way of rewarding customers and attracting new customers. Tier-2 rewards are aimed at influencing the future purchase behavior of customers. Tier-2 rewards are more selective and rewards customers to influence their behavioral and attitudinal loyalty.

Optimal allocation of resources.

The strategy. Ideally, firms should be investing only in customers who are profitable. However, many companies continue to spend resources on a large number of unprofitable customers. They either invest in customers who are easy to acquire but are not necessarily profitable or try to increase the retention rate of all their customers, thereby leading to wastage of limited resources.

Implementation of this strategy calls for identifying the most profitable customers, and the customers who are most responsive to marketing efforts. The second step is to determine the right mix of different channel contacts for each customer. This depends upon how responsive each customer is to these channels of communication (e-mail, direct mail, telephone, direct visit by a salesperson), and how cost effective these channels are. The next step in implementing this strategy is to decide how frequently the customer should be contacted, and what the intercontact time should be. Further, the various factors that affect customer behavior such as upgrading (to a higher product category), cross-selling (in a different category), and so on, need to be analyzed. Therefore, by carefully monitoring the purchase frequency of customers, the interpurchase time, and the contribution toward profits, managers can determine the frequency of marketing initiatives in order to maximize CLV.

Need for the strategy. Conventional wisdom says that a company's contact strategy and the frequency and modes of communications affect the customer's predicted purchase frequency. Further, it would help managers know the extent to which they should use the various contact channels. For instance, should there be an increase in face-to-face meetings

and a decrease in the frequency of direct mailers, or vice versa? Traditional marketing methods of flooding customers with product promotions will not only drain the company's limited marketing resources but also lead to customer estrangement. Venkatesan and Kumar (2004) have shown that different channels of communication have different costs associated with them and have to be employed at the optimum frequency and time intervals to maximize a customer's purchase frequency.

Benefits of the strategy. This strategy makes recommendations as to which customers to acquire and retain based on their predicted CLV. It also provides recommendations as to how to use the different channels of communication based on how responsive each customer is to these channels. And an optimal level of communication across the right mix of channels is recommended in order to achieve maximum profitability. When the channel reallocation was implemented in a B2B firm, the firm generated 100% more revenue and 70% more profit.

Pitching the right product to the right customer at the right time.

The strategy. Companies are constantly involved in predicting the next product that a customer is likely to buy. An ideal contact strategy is one where the firm is able to deliver a sales message that is relevant to the product that is likely to be purchased in the near future by a customer. This could be achieved by accurately predicting the purchase sequence.

Need for the strategy. Understanding the purchase sequence calls for analyzing past customer purchases and estimating the likelihood of future purchases to design optimal contact strategies. By analyzing and asking questions such as (i) in which product category the customer is likely to make a purchase, (ii) at what intervals and at what time period is the customer likely to make a purchase, and (iii) how much is the customer likely to spend or, in other words, how profitable the customer is likely to be, the strategy predicts the purchase sequence of each customer.

Benefits of the strategy. When Kumar, Venkatesan, and Reinartz (2006) tested this in

a B2B setting, 85% of the customers predicted by this model to make a purchase actually went on to do so. In comparison, only 55% of the customers predicted by the traditional model actually made a purchase. When this strategy was implemented in the B2B setting, an increase in ROI of 160% was observed. Thus, this strategy suggests that efficient management of the purchase sequence not only increases revenue by accurately predicting and preempting a customer purchase but also minimizes cost by reducing the frequency of customer contacts.

Preventing customer attrition.

The strategy. As competition intensifies, companies find that their customers are very vulnerable and are likely to defect. Since customer churn has a tremendous impact on the firm's performance it is very critical for the firms to develop a successful strategy to prevent attrition. This strategy calls for calculating the probability of defection for each customer. With this as the base, and answers to questions such as: (i) Should we intervene? (ii) With which customers should we intervene? (iii) When should we intervene? (iv) Through which channel should we intervene? (v) What should we offer? companies can target those customers with intervention offers that would make them stay with the company for a longer period of time.

Need for the strategy. Customer attrition impacts a firm in several ways. First, firms experience a loss of revenue from the customers who have defected. Second, the opportunity cost for the firm to recover the acquisition cost on the defected customer is lost, which makes it difficult for the firm to break even. Third, the firm loses the opportunity to up-sell/cross-sell to customers who have defected, and this loss can be treated as a loss of potential revenue. Fourth, due to potential negative word of mouth, the firm loses out on future customers. This drains the firm's resources, which are already impacted by the loss of customers, mostly to competitors (*see* COMPETITOR ANALYSIS).

Benefits of the strategy. The effect of the customer intervention strategy was studied in a telecom firm using test and control groups. Using

8 customer relationship management

this strategy, the firm realized a net revenue gain of \$345 000, after accounting for the cost of intervention, and the ROI was close to 860%. Therefore, the key to retaining customers is to identify those who are likely to quit and intervene by sending appropriate messages.

Managing multichannel shoppers.

The strategy. This strategy demonstrates that multichannel shoppers (see MULTI-CHANNEL MARKETING) initiate more contacts with the firm, stay with the company for a longer duration, purchase more frequently, and are more receptive to contacts through multiple communication channels. Further, the strategy shows that there exists a nonlinear relationship between returns and multichannel shopping, and that there is a positive synergy toward multichannel shopping when customers are contacted through various communication channels.

Need for the strategy. Companies are in a constant pursuit to grow and serve customers, and thereby use at least a few different channels. In many cases, these channels not only offer customers a chance to make purchases via multiple channels but they also offer customers the chance to search for product information in one or more channels and purchase in a completely different channel. Further, owing to advancements in logistics, increase in online selling formats, and diverse customer segments, firms are introducing multiple distribution channels to target the customer segments. Since each distribution channel services a different set of customers and provides varying levels of services, this approach can lead to a reduction in the overall service cost, resulting in an increase in profitability for the firm. Therefore, it would be profitable for firms to start operating across multiple channels and thereby target the multichannel shoppers.

Benefits of the strategy. Using this strategy, Kumar and Venkatesan (2005) showed that as a customer shops across more channels (from one channel to four channels), the customer (i) spends more revenue with the firm, (ii) spends a higher proportion on the focal firm (rather than with a competitor), (iii) has a higher past profitability (which is correlated with future profitability), and (iv) has a higher likelihood

of buying in the future. By adopting the test and control group experiments, it was found that the net gain in revenue for the firm due to the addition of one more channels was on average about 80%. After accounting for the costs, the return on investment was about eight times or 800%. Therefore, when firms contact the right customers, at the right time, to encourage adopting another channel, it results in higher profitability.

Acquiring profitable customers.

The strategy. The main goal of this strategy is to acquire profitable customers, make them stay longer with the company, and derive more profits from them over their lifetime with the company. Using CLV, this strategy optimizes the acquisition/retention costs of customers and links such efforts to overall profitability. Such an exercise helps firms to decide which customers are worth acquiring/retaining and which dormant customers should be pursued to come back to the firm. Firms should use customer profiles to identify the customers who are most likely to be profitable. This can be achieved by identifying customers with similar characteristics as existing high-CLV customers, and by adopting an appropriate marketing strategy.

Need for this strategy. The need for this strategy arises from the fundamental question to which every company seeks answers – whom to acquire and retain? While making direct marketing investment decisions, many marketers still overemphasize short-term cost over long-term gain. This leads to a situation where companies would pursue customers who are cheap to acquire and cheap to retain without essentially being profitable. Conventionally, most companies use customer acquisition and retention rates to measure their marketing performance. This approach could diminish returns to the firms as they might be spending more on acquiring and retaining a customer, than on what the customer brings in as revenue. Further, different groups of customers require different levels of acquisition/retention spending to maintain their relationship. Therefore, managers need a strategy that strikes a balance by efficiently allocating resources

between customer acquisition and customer retention.

Benefits of this strategy. By observing the customer behavior of a catalog retailer, Thomas, Reinartz, and Kumar (2004) segmented customers on the basis of their cost of acquisition and cost of retention. They found that the largest segment (32%) was made up of customers who were easy to acquire and retain. But, they accounted for only 20% of the total profits. On the other hand, 40% of the total profits came from the smallest group of customers (15%) who were expensive to acquire but cheap to retain. Therefore, linking acquisition and retention to profitability helps the firm to target and retain profitable prospects and customers. This demonstrates that optimal allocation of resources helps companies increase their revenue, balance acquisition and retention strategies, and manage customers profitably.

Referral marketing strategy.

The strategy. This strategy introduces the use of the Customer Referral Value (CRV) metric, which is defined as the value of the referral behavior for a specific customer, as the basis for managing and maximizing customer referral behavior. This metric advises managers that customers be valued on the basis of their indirect impact on the firm's profits, through savings in acquisition costs and addition of new customers by way of customer referral.

Need for the strategy. Past research studies have suggested the existence of a link between a customer's willingness to recommend and the growth in firm's profits (Reichheld, 2003). Specifically, the ultimate question for a firm is – would you recommend us? Relying only on this question leads to two problems: (i) this question would highlight only the correlation and not the causation of referrals and increase in profits, and (ii) this question would identify the referral behavior on an aggregate level and not on an individual customer basis. Recently, Kumar, Petersen, and Leone (2007) conducted a field study to better understand the determinants of customer referral behavior and its impact on firm profits by computing CRV.

Benefits of the strategy. It is important to note that while CLV indicates the actual value of purchases provided by a customer to the firm, CRV computes the influence that the customer has on other potential customers. Therefore, firms should measure and manage CLV and CRV simultaneously to drive more value for the firm. To develop an effective CRM strategy, a telecommunications firm computed the CLV and CRV for a sample of 9900 customers and segmented them into four cells of a 2×2 matrix. The four cells are (i) affluents (high CLV and a low CRV), (ii) misers (low CLV and a low CRV), (iii) advocates (low CLV and a high CRV), and (iv) champions (high CLV and a low CRV).

Therefore, the managerial implications in maximizing CLV and CRV simultaneously is that (i) not all behaviorally loyal customers recommend new customers, (ii) not all customers who recommend new customers are behaviorally loyal, and (iii) focusing only on high-CLV customers for increasing the number of referrals is not an optimal strategy. The key to success is to encourage customers to build social networks and to trigger them, along with customers who already have strong social networks, to talk to individuals in their network by using marketing programs that reward word of mouth and/or referrals.

The strategies discussed here are proven strategies that can help companies in building profitable longerlasting customer relationships. Even though these strategies can yield great results when implemented separately, they work best when implemented as a whole. The knowledge acquired from implementing each strategy can be used to improve on other strategies, and this information can be collectively used to refine future CRM initiatives.

FUTURE OF CUSTOMER RELATIONSHIP MANAGEMENT

Until now, CRM strategies adopted by companies have always focused on cost savings in managing customers. Increasingly, companies are beginning to realize the potential of cultivating profitable customer loyalty that can help them increase revenue and profit. When implementing CRM strategies, firms have to adopt a customer-focused view that considers

their needs, lifetime value, and profitability. In this regard, a product-focused view where decisions are made with the product in reference would be of little help to the companies. Such a managerial transformation requires indentifying necessary components and interfaces for delivery of products/services to the customer, human resources to implement and manage the process, and appropriate metrics that can measure and maximize the impact on any change in the firm's consumer base. The future of CRM, therefore, lies in the ability of firms to accurately assess customer feedback and market trends through an interactive marketing (see DIRECT AND INTERACTIVE MARKETING) approach and the capacity to respond instantly to changing market and customer needs.

ACKNOWLEDGMENTS

The author wishes to thank Bharath Rajan in the preparation of this manuscript. The author thanks several financial services, pharmaceutical, grocery, high tech, telecommunication, and retailer firms for agreeing to share their customer databases for this study.

customer satisfaction/dissatisfaction

Steven P. Brown and William Zahn

CUSTOMER SATISFACTION

Customer satisfaction is a tacit or explicit assessment by customers that they have received positive outcomes and fair value for sacrifices made in acquiring and utilizing a product or service. In fundamental respects, it lies at the heart of marketing thought and practice. Given its centrality to marketing thought and practice, it is not surprising that customer satisfaction has been considered from various perspectives and at different levels of analysis in marketing research. Customer satisfaction research accounts for a substantial proportion of total revenues of leading market research firms (Oliver, 1999), and academic research on the topic provides an integrating theme that can be traced across research paradigms and substantive fields of interest.

Customer satisfaction might fairly be said to constitute the conceptual centerpiece of marketing thought and practice, or at least to have as substantial a claim on that distinction as any other construct. In this article, we organize the many viewpoints that have been taken on customer satisfaction into three categories: philosophical, psychological, and managerial.

The philosophical perspective. In his classic article on “Marketing Myopia,” Levitt (1960) argues that the brilliance for which we remember Henry Ford should *not* be for having revolutionized production processes; it should be for his marketing prowess. Citing Ford’s own writings, Levitt notes that Ford first came to understand that he could sell millions of cars priced at \$500, and only then set out to devise a way to profitably satisfy this latent demand. Assembly line production became the means to this end, but the driving innovation was that the goal of satisfying customer wants and needs at a profit at a price they were willing to pay dictated product design and the means of production. While he was apparently denying it (by saying “customers can have it in any color they want, as long as it is black”), Ford had become the father of MARKET ORIENTATION.

Levitt’s (1960) article is frequently cited as the seminal statement that customer satisfaction and customer orientation lie at the heart of business and constitute its essential purpose. This philosophical position has since been thoroughly interwoven into marketing thought (if not always into practice). It is reflected in Levitt’s observations that “The view that an industry is a customer-satisfying process, not a goods producing process, is vital for all businesspeople to understand” (p. 55), and that “...the entire corporation must be viewed as a customer-creating and customer-satisfying organism. Management must think of itself not as producing products but as providing customer-creating value satisfactions” (p. 56; *see A FRAMEWORK FOR CREATING VALUE PROPOSITIONS*).

Levitt’s philosophical perspective has been updated by Kohli and Jaworski (1990); Narver and Slater (1990), and others in their descriptions of market-oriented organizations (*see MARKET ORIENTATION*). Their contributions, which we discuss in more detail in the section Managerial Perspectives, have supported the philosophical perspective and sustained the role of customer satisfaction as the centerpiece of marketing thought and practice.

Noting that satisfied customers often do not remain brand loyal (*see BRAND EQUITY; BRAND GROWTH STRATEGY*), some writers (e.g., Reicheld, 1996) have urged scholars and managers to redirect their attention from customer satisfaction to loyalty. Addressing this issue, Oliver (1999) underscores the indispensable role of customer satisfaction in the development and maintenance of loyalty (*see CUSTOMER EQUITY*). He likens the metamorphosis from satisfaction into loyalty to the germination of a seed into a flower when nurturing elements (e.g., differentiated quality, social support, and consumer resistance to competitive offerings) are present. He further notes that in many product categories (e.g., those in which real differentiation, customer identification, and social support are not feasible) true loyalty is not realistically achievable, and satisfaction should remain the firm’s primary objective.

2 customer satisfaction/dissatisfaction

The psychological perspective. Feelings and judgments of satisfaction (e.g., with life, work, or relationships, as well as with products and services) importantly influence the quality and meaning of life experience (see THINKING DEEPER ABOUT CUSTOMER EXPERIENCE). As a result, considerable research effort has endeavored to understand the processes that determine satisfaction judgments.

From the psychological perspective, Oliver (1999) defines customer satisfaction as “pleasurable fulfillment.” Research on processes resulting in customer satisfaction has focused largely on the disconfirmation of expectations paradigm. In this view, customers are believed to have preexisting expectations about the performance of products and services and to derive satisfaction judgments based on how their actual consumption experience measures up against these expectations. Positive disconfirmation produces satisfaction, whereas negative disconfirmation leads to dissatisfaction. Although the preponderance of research has shared this general premise, different researchers have posited and tested different types of standards and expectations against which to compare product performance (e.g., desires, ideals, experience-based norms, comparison levels of alternatives).

The disconfirmation of expectations paradigm has been criticized for being too focused on single consumption experiences, excessively cognitive, narrowly individualistic, and overly abstracted from consumption context. Seeking to broaden the scope of customer satisfaction research, Fournier and Mick (1999) contextualized the psychological perspective using ethnographic methods. Although they found some support for disconfirmation processes, their investigation also led to conclusions that customer satisfaction is partially rooted in the life situation and social context of the consumer (see THINKING DEEPER ABOUT CUSTOMER EXPERIENCE). Products that facilitate progress toward higher order goals (e.g., being a good parent, being a consummate professional) and enrich the enjoyment and meaning of social interactions produce satisfaction. Also, products that inspire awe, produce positive surprise and delight, eliminate expected negative consequences of consumption, or become integral

to the consumer’s existence deliver high levels of satisfaction. Fournier and Mick (1999) also found customer satisfaction to result from dynamic processes that are shaped through extended interactions with products over time. In all, this research usefully broadened the psychological perspective on customer satisfaction by highlighting the limitations of the dominant disconfirmation paradigm (while not totally rejecting it) and emphasizing the goal-directed and socioemotional aspects of consumption. They also highlighted what they perceived as an integral linkage between customer satisfaction and life satisfaction (particularly in the sense that products that further life goals produce customer satisfaction).

The managerial perspective. The managerial perspective on customer satisfaction is concerned with the practical realization of the philosophical perspective. If from a philosophical perspective customer satisfaction is a primary goal that shapes product development and means of production, then the managerial perspective is concerned with the means by which this orientation can be implemented most effectively. The ubiquity of customer satisfaction measurement in industry suggests the extent to which executives accept the philosophical perspective and strive to implement it. In contrast to research on the psychological perspective, which is typically conducted at the individual level of analysis, research on the managerial perspective aggregates customer satisfaction scores to the organizational level and seeks to identify antecedents and outcomes of satisfaction at this level.

Fornell and Wernerfelt (1987) provided an important impetus to the managerial perspective on customer satisfaction by indicating the substantial returns firms can realize from “defensive marketing” (i.e., customer retention resulting from high levels of satisfaction; see CUSTOMER RELATIONSHIP MANAGEMENT). Reicheld (1996) provided a further impetus with an analysis indicating that an improvement of 5% in customer retention can result in profitability improvements ranging from 25 to 95% (depending on industry; see CUSTOMER LIFETIME VALUE (CLV)). Although customer loyalty (rather than satisfaction per se) is the

focal variable in these analyses, as previously noted, customer satisfaction is the sine qua non underlying loyalty (in the sense of attitudinal commitment to the brand).

Development of the American Customer Satisfaction Index (ACSI) at the University of Michigan, which benchmarks over 200 firms based on customer satisfaction scores, has importantly advanced research from the management perspective. Studies based largely on the ACSI database have established satisfaction as a leading indicator of financial performance metrics, such as operating margin, return on investment, and shareholder value (e.g., Anderson, Fornell and Mazvancheryl, 2004; *see* MARKETING METRICS). Most of this research has shown meaningful variation in the strength of relationship between satisfaction and financial performance across industries. Other research has shown that customer satisfaction also improves the efficiency of future advertising and promotion investments (Luo and Homburg, 2007; *see* COMMUNICATIONS BUDGETING).

Conceptual and empirical research on market orientation (e.g., Kohli and Jaworski, 1990; Narver and Slater, 1990) has extended Levitt's work by identifying processes that characterize market-oriented businesses and relating them to organizational performance. In Kohli and Jaworski's (1990) framework, these processes include intelligence generation, dissemination across functions, and coordinated response to market developments. Parsing the conceptual domain of market orientation somewhat differently, Narver and Slater's framework includes customer orientation, competitor orientation, and interfunctional coordination. Both of these views of market orientation have been shown to be positively related to firm profitability.

At a finer grained level of analysis, organizations frequently seek to leverage their investments in satisfaction research by identifying specific process improvements that will most effectively improve customer satisfaction. Product attributes that correlate highly with customer satisfaction and on which performance has considerable room for improvement provide the best targets.

Survey-based efforts to improve customer satisfaction have been criticized for being backward looking, as customer feedback reflects past

actions and may provide no hint of impending discontinuous innovations that could render present markets obsolete. In this regard, it is important for firms to maintain a broad vision in their collection and dissemination of market information and not rely excessively on customer feedback about current product forms. Such feedback must be interpreted in the context of latent needs that customers may not be able to articulate easily, and technological advances that could result in new and radically changed product forms that serve the same needs (*see* INNOVATION DIFFUSION). This point was central to Levitt's (1960) original statement of the marketing concept.

SUMMARY

As the core of the marketing concept, customer satisfaction has a reasonable claim to being the conceptual centerpiece of marketing thought and practice. Although some have reasonably argued that "satisfaction is not enough" (i.e., many satisfied customers switch to competitors' products), deep brand loyalty begins with the experience of satisfaction, and without it true loyalty cannot develop. Conversely, dissatisfaction leads to customer defections, negative word of mouth, and even customer efforts to harm the brand.

Given the centrality of customer satisfaction to marketing thought and practice, it is not surprising that it has inspired a great abundance and diversity of research. As our review suggests, widespread acceptance of the marketing concept reflects a philosophical perspective in which delivering customer satisfaction is the fundamental purpose of business. This perspective suggests the importance of understanding the psychological processes that lead to customer satisfaction. In this regard, we conclude (in agreement with Fournier and Mick, 1999) that the dominance of the expectancy disconfirmation paradigm has restricted progress toward a broader and more contextualized appreciation of socioemotional factors that shape the experience of satisfaction. Finally, research conducted at the organizational level of analysis has shown that customer satisfaction is related to a range of financial performance metrics. These findings support the philosophical perspective as

4 customer satisfaction/dissatisfaction

originally articulated by Levitt (1960). As the psychological perspective has suggested, satisfaction importantly influences the nature and quality of people's life experiences, and delivering it reliably to customers is fundamental to firms' financial performance.

customer solutions

Sundar G. Bharadwaj

In the last decade, firms have increasingly moved in the direction of offering solutions to their customers. Recent actions by Dell to purchase Perot Systems, HP in purchasing EDS, or Xerox's purchase of Affiliated Computer Systems were all motivated by the need to offer solutions. This strategic action which initially began in the technology sector has broadened out to other sectors including financial services, travel, healthcare, automotive, and others. Actions such as using reverse auctions, group purchasing, global sourcing, and supplier tiering have increasingly put pressure on supplier firm prices and profitability. To overcome the perceived commoditization that such purchasing approaches impose on their offerings, supplier firms have added solutions to their portfolio with the explicit hope of differentiating their offerings and appropriating the value created through better prices. However, in a vast majority of instances, the expected premium prices have not materialized. The fundamental problem has been the inherent confusion that supplier firms have faced with regard to what a solution really is. Customers have tended to perceive the solutions offerings of their supplier firms merely as bundles largely consisting of products and service that are at best customized. Consequently, customers have not tended to provide the premiums that the suppliers have anticipated for such offerings, while in fact they have demanded a discount for buying a bundle. On the other hand, suppliers have faced increased costs in designing customized bundles and with lower prices their bottomlines have been significantly hurt. The author has drawn upon a study on both customers and managers from supplier firms to present a new way of defining and delivering solutions (Tuli, Kohli, and Bharadwaj, 2007).

The research indicates that while most supplier firms think of a solution as a customized and integrated bundle of goods and services, most customers, in sharp contrast, think of a solution as *a set of relational processes comprising (i) customer requirements definition, (ii) customization and integration of goods*

and/or services, (iii) their deployment, and (iv) postdeployment customer support, all aimed at meeting a customer's business needs. The contrasting viewpoint leads suppliers to under-emphasize customer requirements definition and postdeployment support that are crucial to many customers. Suppliers' inattention to these relational processes appears to result in ineffective solutions, dissatisfied customers, and lower profitability. Viewing a solution as a set of four relational processes can help suppliers organize themselves to deliver greater value to customers, determine their cost-to-serve more accurately, and appropriate the value through more favorable prices.

Understanding a customer's business and needs is a nontrivial task. Firms need to translate the benefits of the solution in terms of outcomes that match the customer needs closely. For example, Lorenzo Zambrano, the CEO of Cemex, a cement manufacturer, realized that their real business was helping customers complete their construction project, not buy cement. While their goal was to sell more cement to low-income customers in Mexico, they also realized (after conducting participant observation research by living with them for a year in Mexico) that customers relied on repatriated funds from family members in the United States. Repatriation was a costly process and transaction costs were as much as 12%. Moreover, the families in Mexico had little expertise overseeing construction process. Cemex innovated a solution for such customers, wherein they provided construction advice, repatriated funds directly to contractors (lowering transactions costs substantially), and developed precast cement blocks and a new type of low-cost slurry to meet the needs of the low-income target market. An obvious managerial lesson is that to encourage an outcome-based thinking in the organization, firms need to get their employees to think of a whole range of related needs a customer faces in completing a task.

The effectiveness of a solution depends on both supplier and customer related structural and process oriented actions as well as characteristics. In particular, suppliers can enhance their ability to provide solutions by (i) adopting contingent hierarchies, in which a business unit with the most to contribute to a particular

2 customer solutions

solution has the authority over other business units for providing that solution; (ii) prespecifying the organizational process for developing solutions; (iii) aligning incentives of functions and units around providing effective solutions; (iv) emphasizing the documentation of customer engagements; and (v) limiting customer contact personnel turnover.

The effectiveness of a solution also depends on a customer's willingness to (i) adapt to a supplier's offerings, (ii) share information about

its internal operations with a supplier, and (iii) share relevant internal political considerations with a supplier. In summary, these factors serve as the segmentation and targeting guideline for suppliers.

database mining and marketing

Maytal Saar-Tsechansky

Database mining refers to the data-driven process of extracting useful patterns or relationships from large databases, usually by means of sophisticated statistical techniques. In the context of marketing, database mining and marketing refers to the application of data mining techniques with the objective of informing marketing decisions, such as direct targeting decisions. In contrast to some traditional marketing modeling approaches, data mining is principally data-driven. That is, it discovers and unravels patterns in data and is not guided by a theory of the underlying domain.

While most data mining techniques are generic and were not specifically developed for marketing applications, marketing has proven to be a popular application for database mining. Indeed, applications of data mining in marketing have been highly successful, and some have even become standard industry solutions. The reasons for this success include (i) the availability of large amounts of clean and structured data (such as scanner, purchase, and click-through data), (ii) open-mindedness regarding the interpretability of models (black box approaches are often acceptable), (iii) moderate requirements regarding the performance of data mining (i.e., the cost of decision or prediction errors is typically not very high), and (iv) significant, measurable, and immediate monetary benefits often result from the application.

Most marketing applications of data mining techniques utilize customer-specific demographic information, customer behavioral records, or a combination of both. The adoption of the Internet as a sales platform and a virtual environment offers a plethora of additional data sources including user-generated content including reviews, blogs, and Facebook, and social networks, all of which bear significant relevance for marketing problems. Below are illustrative marketing database mining applications that have been adopted widely in industry.

Market basket analysis: This employs algorithms that efficiently extract common co-occurrences of product purchases. More

formally, market basket analysis employs algorithms that extract association rules of the form: if A then B, where A and B are sets of products. Such rules are often interpreted as: if one buys the products in A, then one is more likely (than a customer drawn at random) to buy the items in B. Market basket analysis has been applied to support decisions in store design, promotion, and even product recommendations.

Propensity models: These are predictive models that are typically applied to estimate the likelihood of a certain event, such as the likelihood that a customer will purchase a given product, or discontinue a service. Modeling techniques that have performed well include support vector machines, which are particularly effective for large sets of independent variables, and ensemble modeling approaches such as bagging, which effectively exploit extensive transactional histories. Propensity models are useful tools for designing mailing lists and optimizing the use of sales resources by prioritizing customers for targeting.

Customer lifetime value models: These go beyond modeling a customer's single purchase decision and address the long-term effect of retention efforts. Insights from customer lifetime value modeling can be used to optimize pricing and quality of service decisions. *Wallet models* serve a similar purpose and estimate the total budget that a customer has at his or her disposal for a given product category. This information is of general strategic value and can affect both product- and customer-specific pricing and marketing actions.

Ad placement: This is a more recent marketing application of data mining. The objective of ad placement is to match an ad with a relevant online content so as to increase the likelihood that a customer will be influenced by the ad. In this application, methods from information retrieval analysis are often used both for representing content and ads using keyword vectors and for

2 database mining and marketing

capturing the “proximity” of a given content to a set of keywords representing a given ad.

Viral marketing: This capitalizes on customer social networks that are either associated with a product (such as social networks derived by telecommunication providers based on customers’ interactions) or social networks derived from public data sources, such as blogs. Data mining has demonstrated

that explicit social networks as well as networks derived not from actual interactions but based on behavioral similarities provide valuable cues to help predict consumers’ preferences. For example, network neighbors of a customer who has purchased a service were found to be more likely to order the same service in the future. Such networks have also been found to be effective for identifying targets for brand advertisements.

demand elasticity

Ashutosh Prasad

INTRODUCTION

Pricing is an important component of the MARKETING MIX. Here we cover a well established concept with direct implications for PRICING STRATEGY, namely, the price elasticity of demand. Also discussed are the related concepts of cross-price elasticity and income elasticity of demand.

The price elasticity of demand is a measure of consumers' sensitivity to price changes. Demand is said to be more (respectively, less) elastic if there is a large (respectively, small) change in quantity demanded in response to a price change.

The concept of elasticity was introduced by Marshall in 1882. Bartels (1976, p. 11) in *The History of Marketing Thought* writes that "The concept of elasticity was the result of a long development in economic thought. Adam Smith had recognized that demand was not a fixed amount at all prices. Malthus, on the other hand, had a better appreciation of some of the subjective character of demand and recognized what he called "intensity" of demand. Jevons and the Austrians expanded that idea into a theory of diminishing utility. Alfred Marshall later generalized it in the concept of elasticity. His interpretation of demand has long been used by marketing writers as a theoretical basis for selling, advertising, and the promotional work of marketing in general."

Definition of elasticity. The price elasticity of demand (henceforth *elasticity*) is defined as

$$\varepsilon(P) = \frac{\partial D(P)/D(P)}{\partial P/P} = \frac{P}{D(P)} \times \frac{\partial D(P)}{\partial P} \quad (1)$$

where,

P is the price of the product;

$D(P)$ is the quantity demanded at price P , that is, the demand curve for the product. Function arguments are suppressed hereafter when no confusion arises. The possible dependence of demand on additional variables, such as prices of other goods and customers' incomes, explains the use of partial derivatives.

To apply Equation 1 we need a differentiable demand function which can be obtained either from estimation or by assumption. If the demand curve is unknown but a few discrete points on it are given, then an approximation of elasticity, sometimes called the *arc* elasticity of demand, is useful:

$$\varepsilon \approx \frac{\Delta D/D}{\Delta P/P} = \frac{\% \text{ change in demand}}{\% \text{ change in price}} \quad (2)$$

In this context the definition in Equation 1 is referred to as the *point elasticity of demand*. A derivation of the point elasticity and arc elasticity is provided in Example 1.

Example 1. A store observes that the quantity demanded for a product is D_1 units when it is priced at P_1 and D_2 units when it is priced at P_2 . What is the elasticity?

We can compute the point elasticity by assuming a two-parameter demand function that passes through the data points, followed by an application of the elasticity formula in Equation 1. The answer will depend on the chosen demand function. Thus, for the demand function $D(P) = a - bP$, it is $\varepsilon(P) = \frac{(D_1 - D_2)/D(P)}{(P_1 - P_2)/P}$. Note that the elasticity varies along the demand curve. For example, at the midpoint of the data, $(D_1 + D_2)/2$ and $(P_1 + P_2)/2$, the elasticity is $\varepsilon = \frac{D_1 - D_2}{D_1 + D_2} \times \frac{P_1 + P_2}{P_1 - P_2}$.

The alternative to assuming a functional form for demand is to compute the arc elasticity. When using the arc elasticity formula, often the data midpoint $\bar{D} = (D_1 + D_2)/2$ and $\bar{P} = (P_1 + P_2)/2$ is chosen as the reference point from which percentage changes are computed. Then, applying the arc elasticity formula yields $\varepsilon = \frac{D_1 - D_2}{D_1 + D_2} \times \frac{P_1 + P_2}{P_1 - P_2}$. This illustrates that when evaluated at the data midpoint, arc elasticity and point elasticity with linear demand are equivalent. □

If there are more than two data points, regression analysis can be used to first fit a demand curve to the data and then elasticity can be obtained.

Elastic and inelastic demand. From its definition, elasticity will be negative for a downward sloping demand curve. Since this is usually the case, the minus sign is often ignored. For example, when we say that demand is "more

2 demand elasticity

Table 1 Estimated price elasticities of demand.

| <i>Inelastic Demand</i> | <i>Approximately Unit Elastic</i> | <i>Elastic</i> |

(ns = not significant; lr = long-run)

elastic” or has “higher elasticity” the reference is to the magnitude of elasticity. The magnitude, or absolute value, of elasticity is denoted by $|\varepsilon|$. Demand is said to be *elastic* if $|\varepsilon| > 1$, *inelastic* if $|\varepsilon| < 1$, and *unit elastic* if $|\varepsilon| = 1$. Furthermore, demand is *perfectly elastic* if $|\varepsilon| = \infty$ and *perfectly inelastic* if $\varepsilon = 0$. An example of the latter occurs when the demand curve is parallel to the price axis.

Table 1 was constructed from results selected from Houthakker and Taylor’s (1970) analysis of US consumption data to show a few product categories with elastic, inelastic, and unit elastic demands.

A demand curve will generally exhibit different elasticities at different price points. This is illustrated by Example 2.

Example 2. What is the price elasticity of the linear demand function, $D = A - BP$, where A and B are positive constants?

The formula for elasticity yields $\varepsilon = \frac{-BP}{A-BP}$. Thus, elasticity is a function of the price. Figure 1 shows that the linear demand curve is divided into elastic and inelastic regions.

At its highest value, demand has zero elasticity and at its lowest value it is perfectly elastic. As a curiosity, the elasticity at any point on the linear demand curve is equal to the length of the line segment above that point divided by the length below it. □

Measuring demand sensitivity. As an alternative to computing the elasticity, a related measure of consumers’ sensitivity to price changes is the slope of the demand curve $\partial D/\partial P$. Of these two measures, elasticity is often preferred because it is a unitless quantity, which facilitates

comparisons across different products, currencies, and quantities. However, unlike the slope, it is not straightforward to assess elasticity by eyeballing the demand curve, with the exception that when the demand curve is drawn on a log-log graph, the slope will be exactly the elasticity. To see this, consider the function $y = f(x)$, where $y = \ln D$ and $x = \ln P$ are the transformed demand and price variables. Then the slope of this function is given by

$$\frac{\partial y}{\partial x} = \frac{\partial \ln D}{\partial \ln P} = \frac{\partial D/D}{\partial P/P} = \varepsilon$$

One can derive the demand function requirements for elasticity to be constant. Assuming that elasticity is constant, the above equation $\varepsilon = \partial \ln D/\partial \ln P$ can be solved as a differential

Figure 1 Elastic and inelastic regions of a linear demand curve.

equation to give

$$D = KP^\varepsilon$$

where K is independent of price. This demand function, due to its property of constant elasticity at every price point, is called the *constant elasticity demand function* or the *isoelastic demand function*.

Thus, using log-log transformed demand and price data, the estimate of the slope coefficient provides an empirical estimate of elasticity. The data could come from various sources—sales data, panel data, conjoint studies, surveys, and experimental methods have all been used. Econometrically, it may be necessary to control for such things as competitive and product-line prices, endogenous price, heterogeneity, and correlation with other marketing mix variables to improve the validity of the model. Often with multibrand, multisegment demand models, the elasticity is neither a model parameter nor amenable to derivation from the estimated parameters. Then, after estimating the demand function, elasticities for each brand and segment can be numerically evaluated at a few different price points and an average value reported.

In the preceding discussion, the dependent variable is demand or sales, but it could also be the market share. The price variable can also be variously defined, for example, as absolute or relative price, regular or promotional price, or unit price. There is some discussion that promotional price elasticities are higher than regular price elasticities (Blattberg, Briesch, and Fox, 1995). The former is calculated by adding a discount variable and/or a dummy variable to indicate whether the purchase was made when the product was on promotion. As another operationalization issue, elasticity, by definition, should be unchanged whether computed from an incremental increase or an incremental decrease in the price, but the two can give slightly different results due to reference price effects. The effects of different operationalizations and additional factors on the magnitude of elasticity have been studied. Tellis (1988) and Bijmolt, Van Heerde, and Pieters (2005) provide meta-analyses of a large number of econometric studies. In addition, an excellent

discussion of empirical generalizations from elasticity and cross-elasticity research is provided in Hanssens, Parsons, and Schultz (2001, Ch. 8).

OPTIMAL PRICING

Having understood how elasticity is defined and measured, we now turn to the implications of elasticity for pricing beginning with the monopoly setting.

A monopoly firm's profit from selling its product at price P when facing a demand function $D(P)$ and a cost function $C(D(P))$ is $PD(P) - C(D(P))$, that is, the total revenue minus the total cost. The firm's objective is to maximize its profit with respect to price. We assume a downward sloping demand curve and a convex, increasing cost function, both twice differentiable, and denote $D' = \partial D(P)/\partial P$ and $C' = \partial C(D)/\partial D$. The latter is called the *marginal cost* because it is the increase in total cost when one additional unit of the product is sold, or equivalently it is the cost of the last unit sold. The first-order condition for maximum is $(P - C')D' + D = 0$.

If the second-order condition is also satisfied then, from the definition of elasticity, substitute D' by $D\varepsilon/P$ into the first-order condition and it can be rewritten as

$$\frac{P - C'}{P} = \frac{1}{|\varepsilon|} \quad (3)$$

This is sometimes called the *inverse elasticity rule* for pricing. The left-hand side, which is the markup as a proportion of the price, is called the *Lerner Index*. It is a measure of the firm's market power, that is, the ability of the firm to set a price higher than its marginal cost. In comparison, under perfect competition, the firm has no market power and sets price at marginal cost. The right-hand side of the equation is the inverse of the elasticity at that price point. One can conclude that if a product has more elastic demand then, all else being equal, the optimal price will be lower.

Because the Lerner Index is bounded between 0 and 1, the right side of the equation must also be similarly bounded. It follows that $|\varepsilon| \geq 1$. Thus, when faced with inelastic demand, the firm should price higher till the demand becomes elastic. The optimal monopoly price lies in the

4 demand elasticity

elastic portion of the demand curve. This result can also be argued as follows: total revenue is $PD(P)$ and the impact on it of a small increase in price is $PD' + D$, which may be rewritten as $D(1 - |\varepsilon|)$. This impact is 0 for unit elastic demand (implying that revenue is maximized at $|\varepsilon| = 1$), positive for inelastic demand, and negative for elastic demand. With inelastic demand, therefore, price can be increased to generate additional revenue. Thus, governments can more heavily tax goods such as gasoline and alcohol that have more inelastic demand to raise revenues.

Optimal pricing under Cournot competition.

Next, we examine a model of imperfect competition. Suppose there are N competing firms indexed by $i = 1 \dots N$. The total production in the industry is denoted by $Q = \sum_{i=1}^N Q_i$, where firm i produces quantity Q_i . Under Cournot competition, the market price $P(Q)$ is a function of the industry output. Each firm has the objective of maximizing its profit by its choice of output, that is, $\max_{Q_i} P(Q)Q_i - C_i(Q_i)$. The profit maximizing condition for firm i can be written as

$$\frac{P(Q) - C'_i(Q_i)}{P(Q)} = \frac{s_i}{|\varepsilon|} \quad (4)$$

where, $s_i = Q_i/Q$ is firm i 's market share. This equation is an extension of the inverse elasticity rule from the last section. It states that the larger the market share of a firm, and the lower the elasticity, the higher will be its markup.

Aggregating the left-hand side of the equation over all firms in the industry shows how far the industry deviates from perfect competition wherein the markups would be 0. Multiplying both sides of the equation by s_i and summing over firms yields

$$\sum_{i=1}^N \frac{P(Q) - C'_i(Q_i)}{P(Q)} s_i = -\frac{1}{\varepsilon} \sum_{i=1}^N s_i^2 = \frac{HHI}{|\varepsilon|} \quad (5)$$

where, $HHI = \sum_{i=1}^N s_i^2$ is the Hirschman-Herfindahl Index. This index is used by antitrust entities, for example, to assess the impact of a merger. In a market with a large

number of symmetric competitors, the HHI will be close to 0.

The analysis in this section is useful for explaining regular price levels based on the elasticity. Firms would like their demand to be less elastic so that they can charge a higher price without causing a steep drop in demand and thereby improve their profitability. We therefore proceed to examine what factors influence elasticity and how marketers might apply them. Discussions on this topic can also be obtained from pricing textbooks such as Monroe (2003) and Nagle and Hogan (2006).

DETERMINANTS OF ELASTICITY

The demand curve is an aggregation of individual customer's demands and elasticity is a measure of their price sensitivity. Customers will be more price sensitive, that is, more likely to reduce or stop their purchases of a product whose price has increased if they perceive that there are other, attractive substitutes available. Since the perception of substitutability is influenced by such things as customer satisfaction, differentiated positioning, and advertising, elasticity can be a useful measure of the health of the brand.

Type of product. The availability of substitutes may be constrained by the nature of the product category. If the product category is a necessity, such as salt, gasoline, or pharmaceuticals, then it will possibly have inelastic demand because customers have little choice but to make purchases. For similar reasons, addictive product categories such as cigarettes and alcohol tend to exhibit more inelastic demands. In the case of pharmaceuticals, some additional factors explain lower price sensitivity. For example insurance providers absorb part of the cost and furthermore pharmaceuticals, like textbooks, are prescribed by decision makers who do not bear the cost of the purchase.

Consumer characteristics. The availability of substitutes is also influenced by the characteristics of the customers, which may be influenced by targeting decisions. Elasticity can vary by customer segment depending on the substitutes available to each segment. For example, demand for restaurant food is less elastic for tourists than for locals because the former do not have

information about alternatives, the time or inclination to search, or the option to eat at home. A similar contrast exists between loyal shoppers and switchers, where mainly the latter look around for deals. Differentiation on search costs (e.g., retirees vs employed), inventory costs (e.g., home ownership vs not), and transportation costs (e.g., car owners vs others) also exist and they influence the availability of deals to different segments. The firm should examine the possibility of price discrimination between segments with different elasticities.

Influence of marketing mix. Advertising can be used to affect the price elasticity. If advertising serves to inform consumers about substitutes or attract new consumers who are more price sensitive, then its overall effect is to increase elasticity. But when advertising is used to build loyalty, thereby reducing the need to search for substitutes, it should result in lower elasticity. The loyalty building role of advertising is often contrasted with the immediate sales response of promotions. There is some evidence that offering promotions can make consumers more price sensitive over time because they learn to wait for deals. In effect, the firm provides the expectation of a future, cheaper substitute and hurts its sales at regular prices. However, in the case where promotions lead to habit formation, the result should be reduced elasticity.

Scope of market. The magnitude of elasticity will depend on how broadly or narrowly the product category is defined. An analysis of food and manufacturing industries by Pagoulatos and Sorensen (1986) found that industry price elasticities were all in the inelastic range, some examples being meat packing plants (−0.7), fluid milk (−0.17), soft drinks (−0.05), cigarettes (−0.75), roast coffee (−0.12), canned fruits and vegetables (−0.23), and pet food (−0.10). However, marketers operating at the brand level very often face elastic demand. For example, a given brand of table salt can have elastic demand due to consumers switching between brands despite the fact that the category demand remains inelastic.

Variation over time. By the “long run” we mean that consumers have fully adjusted to a price change. Elasticities will often be higher

in the long run than in the short run because more substitutes become available. For example, when the price of gasoline increases, consumers have little immediate choice except to continue purchasing it in the same quantities. In the long run, however, they can respond to the higher price by purchasing more fuel efficient cars. Another issue of dynamics is how price elasticities vary over the product life cycle. This is complicated because not only does the product change over time but so do the competitive forces and the consumer mix at each stage of the product life cycle. If later consumers are more price sensitive, elasticity increases, but if they are more loyal then elasticity decreases. The latter point was argued by Simon (1979) and finds support in Bijmolt, Van Heerde, and Pieters’s (2005) meta-analysis.

Share of budget. Products whose purchases have a smaller impact on the household budget have less elastic demand. Consistent with this, Bijmolt, Van Heerde, and Pieters (2005) conclude that the magnitude of elasticity is consistently higher for durable goods, which are typically large ticket items, than for groceries. The size of the household should also matter in that large households should be more price elastic than smaller households for products such as groceries because the purchases are a larger proportion of their income. This hypothesis is supported in Hoch *et al.* (1995).

CROSS ELASTICITY OF DEMAND

A related concept to the (own-price) elasticity of demand covered so far is the cross-price (or cross-) elasticity of demand. The cross-elasticity of demand is a measure of the sensitivity of the demand of a product to changes in the price of other products in the market. The cross elasticity of the demand of product A to a change in price of product B is defined as

$$\begin{aligned}\eta_{AB} &= \frac{\partial D_A/D_A}{\partial P_B/P_B} = \frac{P_B}{D_A} \times \frac{\partial D_A}{\partial P_B} \\ &\approx \frac{\% \text{ change in } D_A}{\% \text{ change in } P_B}\end{aligned}\quad (6)$$

where $D_A(P_A, P_B)$ is the demand for product A and P_B is the price of product B.

Note that η_{AB} is not identical to η_{BA} . For example, an analysis of grocery store products found that brands could take significant market share away from other brands in the same price-quality tier or in lower tiers through price reductions, but not from brands in the tiers above themselves (Blattberg and Wisniewski, 1989). Sethuraman, Srinivasan, and Kim (1999) found that the cross-elasticities were highest for brands within the same tier.

If customers view two products A and B as substitutable, then an increase in the price of B makes the purchase of product B less attractive and increases the demand for its substitute. Thus, positive cross-elasticity implies that the two products are substitutes and a higher value of cross-elasticity means that they compete strongly. Similarly, negative cross-elasticity means that the products are complements, while zero cross-elasticity means that the products might not be competing for the same customers. Which products compete with each other, and how strongly, is part of *market structure analysis*. Example 3 illustrates the usefulness of cross-elasticities for market structure analysis.

Example 3. For the three brands A, B, and C in a market, what elements of market structure are revealed from Table 2?

(i) Positive cross-elasticities means the brands are substitutes and the magnitudes suggest that A and B compete more strongly with each other than with C. (ii) The cross-elasticities are asymmetric, with brand A less sensitive to the other brands' prices than they are of its. To put this quantitatively, for brand i , *clout* is defined as $\sum_j \eta_{ji}^2$ and *vulnerability* as $\sum_j \eta_{ij}^2$ (Kamakura and Russell, 1989). Brands A, B, and C have clouts {0.4, 0.09, 0.0} and vulnerabilities {0.09, 0.36, 0.05} respectively. (iii) Cross elasticities are much smaller than elasticities. This means that additional sales are obtained either from stockpiling or market or volume expansion, not just from substitution. (iv) The market is not based on logit competition which generates uniform cross-elasticities. But, as in the logit, it is possible that brand A has the highest market share given that it has the lowest elasticity and highest cross-elasticities. \square

The question of how much of the sales increase caused by a promotion can be attributed to purchase acceleration, quantity expansion, or

brand switching is very relevant for retail store promotions because if the increase in sales comes mainly at the expense of competing brands in the store, then the promotion may not be worthwhile for the retailer overall. To explore this issue, Gupta (1988) proposed the following method for decomposition of elasticity. The sales in units of brand j on a shopping trip is stated as

$$\underbrace{D_j}_{\text{Sales of brand } j} = \underbrace{\Pr(I)}_{\text{Prob. of purchase in category}} \times \underbrace{\Pr(C_j|I)}_{\text{Prob. of choosing brand } j \text{ given category incidence}} \times \underbrace{Q_j}_{\text{Quantity bought given purchase of brand } j}$$

Differentiating with respect to price, the elasticity of sales of brand j is $\varepsilon_j = \varepsilon_{Ij} + \varepsilon_{Cj} + \varepsilon_{Qj}$. For coffee data, Gupta (1988) found $\varepsilon_{Ij}/\varepsilon_j = 0.14$ (a measure of purchase acceleration), $\varepsilon_{Qj}/\varepsilon_j = 0.02$ (a measure of quantity acceleration), and $\varepsilon_{Cj}/\varepsilon_j = 0.84$ (a measure of brand switching). Additional commentary on the interpretation of these numbers is provided by Van Heerde, Gupta, and Wittink (2003).

In addition to explaining competitive interactions, cross-elasticities are helpful for pricing a product-line sold by a firm. In the case of a two-product product-line with constant marginal costs c_i , the firm maximizes

$$\max_{P_1, P_2} \sum_i (P_i - c_i) D_i(P_1, P_2) \quad (7)$$

The results suggest that if the product-line is composed of complementary (respectively, substitute) products, the optimal product line prices will be lower (respectively, higher) than the optimal prices in isolation. Simon (1989) and Rao (1993) have formulae that incorporate cross-elasticities for multiproduct pricing.

Applying this type of pricing analysis in practice requires estimating the matrix of elasticities and cross-elasticities. Reibstein and Gatignon (1984), for example, estimate different cross-elasticity formulations to explain the pricing of eggs. Hoch *et al.* (1995) studied many more grocery product categories. Montgomery

Table 2 Matrix of elasticities and cross-elasticities.

| | A | B | C |
|---|------------------------|------------------------|------------------------|
| A | $\varepsilon_A = -2.2$ | $\eta_{AB} = 0.3$ | $\eta_{AC} = 0.05$ |
| B | $\eta_{BA} = 0.6$ | $\varepsilon_B = -2.8$ | $\eta_{BC} = 0.01$ |
| C | $\eta_{CA} = 0.2$ | $\eta_{CB} = 0.1$ | $\varepsilon_C = -3.3$ |

and Rossi (1999) suggest a Bayesian approach for estimating cross-elasticities.

INCOME ELASTICITY OF DEMAND

In addition to prices, demand can be a function of other variables. In this section we consider the impact of income. The constant elasticity demand curves for a duopoly, for example, could be given by $D_i(P_i, P_j, Y) = K_i P_i^{\varepsilon_i} P_j^{\eta_{ij}} Y^{\kappa_i} \forall i, j \in \{1, 2\}, i \neq j$, where Y is a measure of income and other terms are as previously defined. The income elasticity of demand D is defined by

$$\kappa = \frac{\partial D/D}{\partial Y/Y} = \frac{Y}{D} \frac{\partial D}{\partial Y} \approx \frac{\% \text{ change in demand}}{\% \text{ change in income}} \quad (8)$$

If income elasticity is positive, it means that the consumption of the product increases when income increases, and the good is called a *normal good*. For food items such as vegetables, and other necessities, it is observed that $0 < \kappa < 1$, that is, the proportion of budget spent on food decreases as income increases. This is called *Engel's Law*. In contrast, discretionary and luxury goods associated with leisure, recreation, and foreign travel have $\kappa > 1$. Finally, if demand decreases when income rises, the good is called an *inferior good*. For example, if, when income increases, consumers switch from eating potatoes to eating meat, then potatoes are an inferior good.

There is a connection between own elasticity, cross-elasticity, and income elasticity (Mas-Colell, Whinston, and Green, 1995, p. 27). Assume that if prices and income change by the same percentage then the consumer's demand for different goods does not change. Then for any i of the L goods in the market,

$$\varepsilon_i + \sum_{j \neq i} \eta_{ij} + \kappa_i = 0.$$

direct and interactive marketing

Frank J. Mulhern

Direct marketing consists of marketing communications where organizations communicate with consumers or businesses through direct media. Direct media include mail, print catalogs, and telephone. Interactive marketing is an extension of direct marketing into electronic media technologies that provide immediate, two-way communications. Interactive media include e-mail, the Internet, and mobile (wireless) marketing. Direct and interactive marketing can be contrasted with mass media, which communicate with large audiences, and personal selling, which communicates through person-to-person, nonmediated communications.

Compared to mass marketing, direct and interactive marketing allow organizations to communicate with consumers through conversation-like exchanges that generate integrated marketing communications (see INTEGRATED MARKETING COMMUNICATION STRATEGY) across media platforms (Shepard, 1999).

The key dimensions of direct and interactive marketing are as follows:

- *Information-driven:* Direct and interactive communications are typically linked to customer databases containing information on individual customer purchase histories. Customer databases facilitate three key aspects of direct and interactive marketing:
 - *Precise targeting:* The selection of target customers based on the analysis of past purchase behavior.
 - *Customization:* The ability to vary information, messages, prices, or promotions across customers.
 - *Addressability:* The use of the targeted customers' names within communications to achieve personalization.
- *Interactivity:* Interactive media allow for two-way communications between buyers and sellers as exemplified by e-mail and e-commerce web sites. Interactive communications feature the properties of conversations and facilitate ongoing interactions and relationship building.
- *Response mechanism:* Most direct marketing is direct response marketing – communications that contain a *call to action* – a specific request for a behavioral response such as making a purchase.
- *Measurability:* When paired with customer databases, the effects of direct and interactive marketing can be precisely measured, allowing for the evaluation of performance metrics including response rates, incremental sales, and return on investment.

One of the most important components of direct and interactive marketing is the use of information in databases to measure the buying behavior of customers and their value to the firm. As such, direct and interactive marketing blend with CUSTOMER RELATIONSHIP MANAGEMENT to evaluate key metrics of customer behavior including *recency* – how long ago a customer last purchased, *frequency* – the number of times a customer purchased within a time period, and *monetary value* – the dollar value of total purchases in that time period (Hughes, 2005). Database marketers (see DATABASE MINING AND MARKETING) use scoring models that combine such information into a single metric to prioritize who should be targeted. Direct and interactive marketing tactics are then used to solicit response from the consumers with the highest scores. The combination of direct and interactive media with customer databases allows firms to carry out a *long-term contact strategy* – the strategic management of communications with individual consumers over time based on the estimated customer lifetime value (Venkatesan and Kumar, 2004; see CUSTOMER LIFETIME VALUE (CLV)).

As media become more digital, the direct and interactive marketing approach becomes central to marketing (Harden and Heyman, 2009). In short, mass marketing approaches pioneered in the print and broadcast media era yielding to more precise and efficient marketing communications driven by information in customer databases and the capabilities of interactive media technologies. As television becomes digital and merges with the Internet, the direct and database marketing model will dominate advertising and bring about more

2 direct and interactive marketing

complete MULTICHANNEL MARKETING. In many ways, direct and database marketing represent a revolution in marketing practices that feature a high level of information and the ability to communicate interactively with individual customers.

The limitations of direct and database marketing stem from intrusiveness and customer privacy. Direct and interactive media can be very bothersome to consumers who receive an abundance of unwanted telephone calls, mails, e-mails, and online ads. Privacy concerns are the most serious challenge to direct and interactive marketing (Peltier, Milne, and Phelps, 2009). Many consumers oppose the collection and use of extensive information on their purchase behavior. Direct marketers, in conjunction with the Direct Marketing Association, facilitate mechanisms to protect consumer privacy. A common practice, particularly for mobile direct marketing, is to

limit direct marketing to consumers who opt-in to solicitations from specific brands.

e-commerce and Internet marketing

Adel I. El-Ansary

The advent of the Internet transformed traditional, localized “market places” into vast contemporary global “market spaces.” The transition has been enabled by features that characterize the Internet such as digitization, interconnectivity, interactivity, global reach, time-free and location-free access, personalization and customization, and market deconstruction. Market deconstruction is of particular significance because it leads to the creation of infomediaries that replace and/or supplement the traditional “brick and mortar” marketing channels. These features singlehandedly or in combinations, facilitate the effective and efficient formulation and implementation of business strategy in general and marketing strategy in particular. Examples include (i) market segmentation and targeting through the creation of Internet “communities” powered by blogs and social media, (ii) one-on-one customer reach and interactive buying and selling through “e-commerce” portals, (iii) differentiation and positioning through “online advertising” and enabling customization and personalization on Internet portals, (iv) “online branding” (*see* BRAND COMMUNITY), and (v) marketing program implementation involving online catalog merchandizing, advertising, sales promotion, public relations, and the delivery of digitized products such as music, books, and software. In essence, the Internet established the foundation for building “new, narrowcast media” that enables firms to target customers through one-to-one communication.

E-commerce, enabling buying and selling transactions via the Internet, has shaped the way the world does business, making marketing more competitive, economic, and widespread. Businesses depend on the Internet to reach customers around the world and to market their products to every geographic location with access to the Internet. Businesses are realizing more than ever before that the customer’s priority is the value (*see* CUSTOMER SATISFACTION) of a product. The Internet enables value creation through “portal content,” “e-enabled” customer service, and

“e-enabled” customer relations. The Internet also facilitates communication of value through an “e-integrated marketing communication mix” that includes (i) three-dimensional “online catalog merchandizing,” (ii) online advertising that reaches targeted viewers around the world at a fraction of the cost of the “shotgun” advertisements in magazines, newspapers, and other media, (iii) online sales promotions designed to attract new business with discounts, coupons, and sweepstakes, and (iv) online publication of newsletters and other public relations tools.

The arrival of the Internet shifted power from the marketers to the consumers. Consumers have the ability to search the web for the best deals and products. Consumers are not bound by their geographic location or distance from the seller. The Internet provides unlimited information to consumers and grants them the ultimate purchasing power. Customers enjoy the ability to research information (*see* KNOWLEDGE ACCESSIBILITY) about the product on the Internet, compare prices, and make purchasing decisions. They can access information 24 hours a day, 7 days a week and are thus no longer limited by brick and mortar store hours. Prospective consumers can even view inventory and ship products to their doorstep. One of the greatest conveniences afforded by e-commerce and the Internet is the time savings for the consumer. Customers no longer have to search for a product and waste precious time comparing prices. With a single search on the Internet, consumers can view all available products and compare prices. Also, marketers can easily gather information from customers and process such information using countless analytical tools (*see* WEB SURVEYS) to better understand buyer attitudes, motives, consumption patterns and buying decision making, and behavior. Such analysis is essential for marketers to effectively and efficiently reach buyers. Consequently, marketers are more aware than ever before of what consumers’ *desire*. (*see* CONSUMER DESIRE)

E-commerce and Internet marketing brings additional benefits and revenue to the firm. Businesses can communicate with customers, via email. They can answer customer questions, mitigate buyer concerns, and address problems

2 e-commerce and Internet marketing

more effectively. Customers can provide feedback to businesses, allowing companies to gain a better grasp of their performance and *learn* (see CONSUMER EXPERTISE) how to improve the way they do business. In light of all these benefits, some firms only sell their products online (see ONLINE CONSUMPTION), and therefore have decreased sales costs and customer service costs. Because people around the world are able to view the products that a business offers (see DIGITAL MEDIUM AND GLOBAL MARKETING), a broader market is reached and more sales transactions are likely to occur.

E-business has not always been accepted; however, companies around the globe are realizing, more than ever before, that e-commerce is essential to their survival and their ability to thrive in a globally competitive market space.

It is becoming a truism that the Internet is an equalizer of businesses, large and small, in countries, developed and underdeveloped. In essence, the Internet aids in establishing an “information-based democracy” (see CONSUMER WELL-BEING), enabling participation by everyone everywhere.

ethical marketing and marketing strategy

Gene R. Laczniak and Patrick E. Murphy

INTRODUCTION

Ethical marketing can be defined as practices that emphasize “transparent, trustworthy, and responsible personal and/or organizational marketing policies and actions that exhibit integrity as well as fairness to consumers and other stakeholders” (Murphy *et al.*, 2005). This definition reflects the *normative* dimension of marketing ethics; that is, it embodies an aspirational view of how marketers *ought to* oversee their actions, programs, and procedures as they strategically engage their target markets. The approach is consistent with the motivational spirit of professional codes for marketing practitioners such as the American Marketing Association (AMA) Statement of Ethics (2008), which asks members to commit themselves to embracing “the highest standards of professional norms and values implied by our responsibilities to multiple stakeholders ...”

Of course, like with most statements of ideals, the difficulty and debate occurs in the details and interpretation of complex concepts such as *transparency*, *integrity*, creating trust, and determining the meaning of *fairness* in particular exchange situations. In the points that follow, we try to make more pragmatic and tangible the conceptual dimensions that underscore the essentials of ethical marketing strategy. This is done in three ways. First, we distill the notion of normative ethical marketing into seven basic propositions (BPs) (Laczniak and Murphy, 2006) (referenced as LM, hereafter). Then, we link these propositions to actual company approaches that have been acclaimed as “best practices” in marketing ethics (Klein, Laczniak, and Murphy, 2006). Third, both of these perspectives will also be connected to the AMA Statement of Ethics (2008) in order to underscore the contention that there exist distinct norms and values to which professional marketers are expected to conform.

Some further words about this blended approach to clarifying the nature of ethical marketing are in order. In LM, the authors set about reviewing various frameworks in moral

philosophy and models of corporate social responsibility (CSR) in order to derive the BPs that comprise ethical marketing. This is analogous to the promulgation of principles essential to informed marketing management such as “understand consumer needs,” “segment markets according to meaningful criteria,” and “measure customer satisfaction.” Like most sets of marketing principles, the normative moral perspectives discussed in this article are “integrative” in that each informs and supplements the others.

Klein, Laczniak, and Murphy (2006) examine in detail the practices of over a dozen companies that have been designated as “ethical exemplars” either by winning the *Torch Award* of the U.S. Better Business Bureau or being so anointed in various case study analyses of role-model organizations. Thus, this second approach represents a “boots on the ground” description of how acclaimed organizations implement distinctive ethical marketing practices.

Finally, the AMA Statement of Ethics (2008) captures the fundamental norms and values that professional marketing practitioners should follow (See Table 1 – AMA Statement.) These values are explicated further into a “duty-based” set of expectations that professional marketers ought to adhere to. To the extent that the ethical precepts of the three approaches sketched above converge, we begin to build a strong case for the face validity of certain practices being essential to ethical marketing strategy. The following also must be stated: whether or not *being ethical* contributes to the profitability of marketing strategy is rather beside the point since the expectation is that marketers will practice their craft in conformance to legal requirements and ethical standards. That said, we believe that ethical marketing and improved long-term profitability are tethered as we have argued at length elsewhere (Murphy *et al.*, 2005). Indeed, as Aaker (2008) observes, “Strategy has to win not only in today’s marketplace but in tomorrow’s when the customer, the competitor set, and the market context may all be different.” One way of generating such ongoing, strategic competitive advantage is for the firm to build an enduring reputation of trust in the marketplace that translates to brand loyalty and brand equity. With this in

2 ethical marketing and marketing strategy

mind, we unfold the elements that can help create such abiding trust in the marketing firm.

ETHICAL MARKETING PUTS PEOPLE FIRST

That “good” marketing is *person focused* is the first basic perspective of ethical marketing; it is referred to as the “*societal benefit*” BP (LM). Marketing theory has long placed effective marketing as something more than the *financially focused* view of maximizing profit for owner-investors. Moreover, marketing has always elevated the customer to a status coequal to that of shareholders. As marketing luminary Peter Drucker (1954) wisely opined, “There is only one valid definition of business purpose: to create a customer” (p. 37). Indeed the fundamental tenet underlying modern marketing has always been the marketing concept and its strategic implication that marketing planning is driven by the discovered needs and desires of consumers (Anderson, 1982). From that perspective it also follows that, strategically, organizational resources should be aligned in a manner that creates sustainable competitive advantage for the firm (Porter, 1998). As marketing strategy became more networked and outsourced (Dyer, Kale, and Singh, 2001), the recognition that other stakeholders were essential to marketing success became more prevalent. Today, the enlightened marketing organization realizes that (as Laczniak and Murphy, 2006 restate BP1), “persons in marketing transactions should never be viewed as merely a means to a profitable end” (p. 159).

This deep concern for the welfare of all parties to the marketing process can be seen in the practices of various acclaimed companies (Klein, Laczniak, and Murphy, 2006). For example, Charter Manufacturing Company of Mequon, Wisconsin uses a “cost-plus” pricing model that includes posting the indices from which price is derived on the Web for client-customers to better understand and monitor. Charter also gives its employees a great deal of autonomy both to do their own jobs and also to oversee their clients. And, Tom’s of Maine (ToM), a company producing all-natural personal care products since 1970, includes the statement “People and nature have inherent worth and deserve respect”

as part of their guiding “seven intentions” of “value-centered leadership”. ToM had been named for 10 consecutive years as one of the “100 Best” companies to work for by *Working Mother* magazine.

The general sentiment of “ethical marketing puts people first” is also reflected in multiple passages of the AMA Statement of Ethics (2008) including the elaborations under the value of *respect* that marketers should strive to: “listen to the needs of customers and make every effort to monitor and improve their satisfaction . . .” and “treat everyone, including our competitors, as we would wish to be treated.”

ETHICAL RESPONSIBILITY EXCEEDS LEGAL REQUIREMENTS

Ethical marketing seeks to achieve a behavioral standard in excess of the law. This is the second BP of ethical marketing as defined in LM. It should be understood that the legal system of developed economies is typically a “lagging” institution and, as a result, ethical perceptions of currently controversial marketing practices inevitability foreshadow the future of the law. As a result, marketers need to be proactive in identifying what these marketing-connected problems are and fix them quickly. Moreover, any corpus of professional knowledge, since it reflects its own common body of specialized information, ought to also include guidelines that articulate its unique ethical obligations. Embedded within this BP is the recognition of an implicit “social contract.” This social contract, which takes the form of recognizing the considerable societal impacts of marketing practice (i.e., effective exchange, creation of markets, service innovation, and marketing jobs), also requires accepting substantial social responsibility that supersedes economic efficiency alone (see for instance, Dunfee, Smith, and Ross, 1999). In other words, as a major player in economic system, Marketing has the obligation to work to make that system better – to discharge its “duty of beneficence” as philosopher W.D. Ross (1930) might phrase it.

GSD&M, an advertising agency out of Austin, Texas founded in 1971, seems to be an example of a firm that willingly goes beyond the requirements of the law. Not only do they chisel their

Table 1 AMA Statement of Ethics (*AMA Statement of Ethics (revised 2008)*).

| Ethical Norms and Values for Marketers |
|--|
| <p>Preamble</p> <p>The American Marketing Association commits itself to promoting the highest standard of professional ethical norms and values for its members (practitioners, academics, and students). Norms are established standards of conduct that are expected and maintained by society and/or professional organizations. Values represent the collective conception of what communities find desirable, important and morally proper. Values also serve as the criteria for evaluating our own personal actions and the actions of others. As marketers, we recognize that we not only serve our organizations but also act as stewards of society in creating, facilitating and executing the transactions that are part of the greater economy. In this role, marketers are expected to embrace the highest professional ethical norms and the ethical values implied by our responsibility toward multiple stakeholders (e.g., customers, employees, investors, peers, channel members, regulators, and the host community).</p> |
| <p>Ethical Norms</p> <p>As marketers, we must:</p> <ul style="list-style-type: none">• Do no harm. This means consciously avoiding harmful actions or omissions by embodying high ethical standards and adhering to all applicable laws and regulations in the choices we make.• Foster trust in the marketing system. This means striving for good faith and fair dealing so as to contribute toward the efficacy of the exchange process as well as avoiding deception in product design, pricing, communication, and delivery of distribution.• Embrace ethical values. This means building relationships and enhancing consumer confidence in the integrity of marketing by affirming these core values: honesty, responsibility, fairness, respect, transparency, and citizenship. |
| <p>Ethical Values</p> <p>Honesty – to be forthright in dealings with customers and stakeholders. To this end, we will:</p> <ul style="list-style-type: none">• Strive to be truthful in all situations and at all times.• Offer products of value that do what we claim in our communications.• Stand behind our products if they fail to deliver their claimed benefits.• Honor our explicit and implicit commitments and promises. <p>Responsibility – to accept the consequences of our marketing decisions and strategies. To this end, we will:</p> <ul style="list-style-type: none">• Strive to serve the needs of customers.• Avoid using coercion with all stakeholders.• Acknowledge the social obligations to stakeholders that come with increased marketing and economic power.• Recognize our special commitments to vulnerable market segments such as children, seniors, the economically impoverished, market illiterates and others who may be substantially disadvantaged.• Consider environmental stewardship in our decision making. <p>Fairness – to balance justly the needs of the buyer with the interests of the seller. To this end, we will:</p> <ul style="list-style-type: none">• Represent products in a clear way in selling, advertising and other forms of communication; this includes the avoidance of false, misleading, and deceptive promotion.• Reject manipulations and sales tactics that harm customer trust. |

Table 1 (Continued).

| Ethical Norms and Values for Marketers |
|--|
| <ul style="list-style-type: none">● Refuse to engage in price fixing, predatory pricing, price gouging, or “bait-and-switch” tactics.● Avoid knowing participation in conflicts of interest.● Seek to protect the private information of customers, employees, and partners. <p>Respect – to acknowledge the basic human dignity of all stakeholders. To this end, we will:</p> <ul style="list-style-type: none">● Value individual differences and avoid stereotyping customers or depicting demographic groups (e.g., gender, race, sexual orientation) in a negative or dehumanizing way.● Listen to the needs of customers and make all reasonable efforts to monitor and improve their satisfaction on an ongoing basis.● Make every effort to understand and respectfully treat buyers, suppliers, intermediaries and distributors from all cultures.● Acknowledge the contributions of others, such as consultants, employees, and coworkers, to marketing endeavors.● Treat everyone, including our competitors, as we would wish to be treated. <p>Transparency – to create a spirit of openness in marketing operations. To this end, we will:</p> <ul style="list-style-type: none">● Strive to communicate clearly with all constituencies.● Accept constructive criticism from customers and other stakeholders.● Explain and take appropriate action regarding significant product or service risks, component substitutions, or other foreseeable eventualities that could affect customers or their perception of the purchase decision.● Disclose list prices and terms of financing as well as available price deals and adjustments. <p>Citizenship – to fulfill the economic, legal, philanthropic, and societal responsibilities that serve stakeholders. To this end, we will:</p> <ul style="list-style-type: none">● Strive to protect the ecological environment in the execution of marketing campaigns.● Give back to the community through volunteerism and charitable donations.● Contribute to the overall betterment of marketing and its reputation.● Urge supply chain members to ensure that trade is fair for all participants, including producers in developing countries. <p>Implementation</p> <p>We expect AMA members to be courageous and proactive in leading and/or aiding their organizations in the fulfillment of the explicit and implicit promises made to those stakeholders. We recognize that every industry sector and marketing subdiscipline (e.g., marketing research, e-commerce, Internet selling, direct marketing, and advertising) has its own specific ethical issues that require policies and commentary. An array of such codes can be accessed through links on the AMA Web site. Consistent with the principle of subsidiarity (solving issues at the level where the expertise resides), we encourage all such groups to develop and/or refine their industry and discipline-specific codes of ethics to supplement these guiding ethical norms and values.</p> |

values into the foyer of their building (e.g., “Integrity – do the right thing”) but they have turned down potential clients because partners at the firm were uncomfortable with what they were being asked to do. Similarly, Weber O’Brien, an accounting firm from Toledo, Ohio with 46 associates, has periodically terminated contracts

when clients were found to be lying or cheating; they also offer substantially reduced fees to charitable organizations seeking accounting services (Klein, Laczniak, and Murphy, 2006).

Consistent with this BP, the AMA Statement of Ethics underscores the value of *citizenship*, which calls on marketers “to fulfill the economic,

legal, philanthropic, and social responsibilities that serve stakeholders” and includes the admonition to “contribute to the overall betterment of marketing and its reputation” (American Marketing Association, 2008).

ETHICAL MARKETING CONSIDERS INTENT, MEANS, AND ENDS

BP3 states that *marketers are responsible for whatever they intend as a means or end of a marketing action*. Further, if the intended means and end are acceptable, the action may proceed (with minor side-effects) unless there is risk of a major negative outcome for stakeholders. If such a major negative outcome occurs, even if it was not foreseen, marketers have a responsibility to try to make things right. LM explicate this idea by underscoring the obligation of all marketers to take responsibility for both how they conduct their marketing campaigns as well owning up to any negative social effects that result from their marketing activities, especially when these outcomes are foreseeable and substantial. For example, marketers of fast food and other high-fat/high-salt food snack sellers obviously are not singularly responsible for the obesity epidemic among children in the United States. Clearly, unbalanced eating habits, the lack of exercise, and too much time spent in front of computer or TV are major contributory factors; nevertheless, high calorie, possibly addictive junk food, is somewhere in the causal mix. Thus, according to this BP, marketers should be prudent about the manner in which they promote junk food and fast food and ought to take proactive steps to offer healthy alternatives as well as “smart-eating” advice.

Klein, Lacznia, and Murphy (2006) have profiled several firms that seem to go far beyond the black letter law in taking into account their responsibilities. For example, Toledo Metal Spinning, an industrial fabrications producer in business since 1929, totally lost their major production and operations facility in a 1998 fire. In an action reminiscent of the well-known Malden Mills case, they kept their employees fully engaged in salvage, cleanup, and reconstruction for seven months until a new facility was ready, all with an eye to making progress toward fulfilling the 500 orders that they had “in

process” with an array of customers. Similarly, Baxter International (est. 1931), a global supplier of medical technologies and health care products, was quick to assume the product liabilities to injured patients from defective dialysis filters even though Baxter had only recently acquired the rights to the problematic product line from another company.

The AMA Statement of Ethics (2008) speaks of this disposition toward responsibility quite explicitly. The first *general* norm of the statement is “Do no harm,” the most common ethical dictum across a variety of codes in the professions including medicine and engineering. And, under the value of *transparency* the AMA statement also reads as follows:

Explain and take appropriate action regarding significant product and service risks, component substitutions or other foreseeable eventualities that could affect customers and their perceptions of the purchase decision.

ETHICAL MARKETERS TRY TO INSPIRE MORAL IMAGINATION

The fourth BP focuses on categorizing marketing managers according to their level of moral reasoning. In most firms, managers making marketing decisions differ in their ability to evaluate and resolve ethical issues. Some marketing executives will have little ethical sensitivity while others will have the capacity for significant *moral imagination* – that is, the character and ability to morally reason to creative ethical solutions when encountering an ethical issue (Werhane, 1999). Life experiences, personal values, and basic character traits vary among marketing managers and influence their critical ethical evaluations. *Thus, organizations should seek to understand the nature of these different moral aptitudes and work to instill an improved ethical reasoning capacity among all their managers.*

Inspired by the work of Kohlberg (1969) and others, LM classify marketing managers into four major types detailed below.

- *Egoist marketing managers* are the least morally developed and have a strong tendency to resolve ethical situations on the basis of their own immediate interests and

6 ethical marketing and marketing strategy

consequences. Individuals at this comparatively undeveloped stage of moral thinking give strong weighting to the incentive and sanctions that will affect only them. They use rationalizations such as “everyone else is doing it” and “we were only following orders.”

- *Legalist marketing managers* overtly espouse the law as their guide in adjudicating the propriety of any marketing action. As hinted at in BP2, they embrace predominately an agency approach to their managerial duties and generally follow the adage that “If it is legal, it is ethical.”
- *Moral strivers* are those marketing managers who have progressed in their moral thinking and development to the point where they are capable of considering and balancing multiple stakeholder claims when deciding what constitutes an ethical imperative. Empathy for others is what distinguishes moral strivers from the lower levels. However, without sufficient reinforcement by company ethical standards and training, some strivers will fall back to legalist or egoist tendencies.
- *Principled marketing managers* have reached a high level of moral development. Managers who attain this sophisticated state address their ethical problems by regularly applying both prevailing ethical norms and applicable laws to the specific situation. They possess substantial moral imagination and bring this to bear on their decisions. Like Maslow’s “self actualization” stage, few managers reach this highest level of development (p. 163).

While these four categories are rough approximations, one can see their relevance to marketing management. Recent examples of egoist marketing managers are those from Merrill Lynch and AIG who were “secretly” rewarded with bonuses. Almost 700 Merrill managers received bonuses of around \$1 million while 14 individuals received a combined \$249 million (Bray, 2009). Then in March of 2009, while the Federal government presumptively owned busted insurance company AIG, their traders (who had lost tens of billions of dollars with their earlier derivative-based trades)

were given over \$100 million in bonuses by management in order to incentivize their retention. Recognizing the frail state of the US economy and the fact that both Merrill and AIG were part of the US government bailout in 2008–2009, these episodes may supplant the vilified Enron managers as the personification of ethical egoism even as the term “corporate swine” embodied the lexicon of public outrage.

Somewhat on safer ground, *legalist* managers are quick to fall back on the law as the guiding force for all decisions. Generally, marketing managers in the building and construction sector are known for their letter-of-the-law tendencies perhaps because of their engineering background, a get-the-job-done mentality, and the process-dominated nature of that industry.

Most marketing managers fall into the *moral striver* category. Some of the recent strategic adjustments in the food industry, responding to critics who assert that consumer packaged goods companies are not sensitive enough to the growing obesity epidemic in the United States, are indicative of moral striving. One recent positive response comes from SuperValu, a major Midwestern supermarket chain, which is putting color-coded labels on its store brands to help consumers make a more informed choice regarding fat, sugar, calorie count, and other nutritional content.

While it is perilous to label all managers within a particular firm as “*principled*,” two companies are used to illustrate this stage. The first is Honest Tea. The company was founded as a competitive response to the then typical flavored, cold teas that were generally high in sugar and low in nutrition content. The original (Honest Tea) product was made from whole tea leaves, which leads to better taste. The name fits this all-natural product because it strived to create healthy *and honest* relationships with multiple stakeholders – customers, suppliers, and the environment. (In fact, the original name was Honestea, but the threat of a lawsuit by Nestea forced the change). Furthermore, in order to enhance distributive justice in the supply chain, the company buys “fair trade” tea from around the world and partners with nonprofit organizations in selling some of its flavors. Honest Tea also invented and uses tea bags with a one-piece, tag-and-bag design and no staple or

string, making them fully biodegradable. The bag itself is made with unbleached fiber from an abacca plant (Klein, Laczniak, and Murphy, 2006). These principled policies led to financial success for Honest Tea, and in 2008, Coca Cola purchased a 20% stake in the firm.

The second company example is Lego, the well-known Danish toy brick producer. The name of the company means to “play well.” Its managers have long followed principles such as only depicting toys on the box that can be assembled from the bricks inside and never having larger pictures on the outside of the box than “actual size” so that the children never will be misled. In recent years, Lego also has become a signatory and proponent of the UN Global Compact. The principles espoused there deal with child labor, health, and safety, and protection of the environment. Lego has also developed its own set of principles to guide its relationship with suppliers. While no company is perfect, Lego does seem to demonstrate in multiple ways that they are a “principle-based,” ethically driven company.

The four types of marketing managers described above relate to the AMA Statement of Ethics in that the Association hopes that by following the ethical values outlined within, professional marketing managers will be pushed toward the “principled stage” of moral development. In fact, the “Preamble” to the American Marketing Association (2008) statement indicates that “marketers are expected to embrace the highest professional ethical norms and the ethical values implied by our responsibility toward multiple stakeholders . . .”

ETHICAL MARKETERS EMBRACE CORE VALUES

With the formulation of BP5, LM suggest that “Marketers who aspire to operate on a high ethical plane should articulate and embrace a core set of ethical principles.” There, five principles are recommended including the *principle of nonmaleficance*, basically not intentionally doing harm via marketing actions, policies, and procedures, and the *principle of nondeception* – avoidance of intentional misrepresentation to or unfair manipulation of consumers. Both these precepts are reflective of the general norms (for

good and fair marketing) specified in the American Marketing Association (2008) Statement of Ethics. In addition, three other principles are put forward in LM that challenge marketing practitioners to aspire to even greater levels of social responsibility. These are as follows:

- *The principle of protecting vulnerable markets:* Marketers must always take extraordinary care when engaging in exchanges with vulnerable [market] segments.
- *The principle of distributive justice:* There is an obligation on the part of all marketing organizations to assess the fairness of marketplace consequences flowing from . . . marketing practice.
- *The principle of stewardship:* Marketers are obligated to ensure that their operations will not impose external costs on society, especially the physical environment, that result from their . . . marketing [actions].

As documented by Klein, Laczniak, and Murphy (2006), there are multiple instances of organizations that attempt to formulate, embrace, and follow such core principles as part of their corporate mission and culture. For example, BadgerMeter, a Milwaukee-based manufacturer of water meters and flow technology that sells its products worldwide, has long held three guiding principles: (i) exemplary ethical conduct, (ii) respect for all people, and (iii) managing for the long term. These ideas are expanded in a detailed corporate code of conduct but interestingly, the organization specifies that all of its core vision can be realized by caring for each customer as if it were one of its “hometown” Milwaukee neighbors. Similarly, ToM, the producer and seller of natural and environmentally compatible personal-care and household products mentioned earlier, has articulated a “managing upside down” approach that begins with the assumption that “people and nature have inherent worth and deserve respect.” This idea is at the heart of its “value-centered leadership” approach that encourages ToM managers to “connect with goodness” as the true path to economic success.

A particularly interesting example is bp, the energy sector multinational (i.e., the former British Petroleum), because it both illustrates

the importance of having core values as well as the reality that espousing these is not enough to insure ethical behavior. bp is an organization that, in the mid-2000s, experienced a horrific explosion at its Texas refinery resulting from employee inattention as well as pipeline damage in Alaska, due to its lack of following required safety procedures. That said, there was no doubt within the bp organization that what happened was an ethical failure because bp has taken great pains to document not only its core values (e.g., trust, acceptance of the UN Declaration of Human Rights) but also a decision-making framework that should be consulted along the way. This decision model, internally sometimes referred to as the “bp Way,” makes clear that “there is no right way to do a wrong thing” and that any uncertainty about the ethicality of a contemplated decision requires greater consultation within the company.

ETHICAL MARKETERS ACCEPT THE STAKEHOLDER CONCEPT

The notion of a stakeholder (i.e., any group or individual who can affect, or is affected by, the achievement of the organization’s objectives) was introduced to the business literature by Freeman (1984). Since that time, marketing managers and other senior executives have focused attention on those who have a “stake” in business decisions. It can be logically reasoned that *the adoption of a stakeholder orientation is essential to the advancement and maintenance of ethical decision making in all marketing operations*. Such an orientation embodies the idea that marketing organizations operate in and on behalf of society (Laczniak and Murphy, 2006). In the sixth BP, LM recognize three primary and three secondary stakeholders. Not surprisingly, customers, employees, and investors are the three primary stakeholder groups identified. These groups are primary because they are typically necessary to the completion of successful marketplace transactions and their claims trump other stakeholders. The three secondary stakeholders identified are distributors/suppliers (some of whom have contractual relationships with the marketing organization and are essential partners to the well-being of the firm) as well as host communities and the general public.

While many companies have not only embraced the stakeholder concept but also worked to genuinely “engage” in stakeholder dialogue, noted here are firms that have done a particularly superior job of addressing the needs of one of the six stakeholder groups. For example, customer orientation is a hallmark of many successful commercial marketers such as Johnson & Johnson. J&J’s stakeholders include doctors, nurses, patients, mothers, and fathers and are given primacy in their famous Corporate Credo. Similarly, Harley Davidson – that famous international icon of customer admiration – is known worldwide for the brand loyalty and customer appreciation connected to that organization. In the nonprofit world, the Mayo Clinic is recognized as being unparalleled in its patient orientation (Berry and Seltman, 2008). Perhaps, the best national example of focusing on the employee stakeholder is Southwest Airlines, a firm espousing the philosophy that “satisfied employees lead to satisfied customers.” Also, Charter Manufacturing, identified earlier in this article, is a regional company illustration of a firm that accords its employees exceptional autonomy and respect. In contrast, a purely investor orientation is extremely well practiced by investment banks like Goldman Sachs – putting its investors (and some would say its management) above the needs of the market/consumers and sometimes taking advantage of its competitors in the process. The current state of the world’s financial markets shows the catastrophic effect of only focusing on short-term investor stakeholders.

In the secondary stakeholder category, Toyota is known for its strong relationships with its suppliers and dealers. Similarly, Target and General Mills, headquartered in Minnesota, are renowned for responding with empathy to their (secondary) community stakeholders via their generous philanthropic policies. They and many other companies in that geographic area donate 5% of pretax profits to charity, much of it going to nonprofit corporations. The general public, as yet another secondary stakeholder, is often embodied by the media or advocacy groups. Two companies that have constructively engaged their secondary stakeholder critics during the last several years are Nike and Wal-Mart. In the late 1990s, Nike was widely vilified for

the working conditions of its subcontractors, especially those in the developing world. The company embarked on a major effort to negotiate with representatives of several human rights activist groups in order to improve the situation. A more recent illustration is Wal-Mart and its environmental critics. The firm has not only engaged these stakeholders, but made bona fide efforts to become a “green” company and to stock and sell products that are increasingly environmentally friendly (Rosenbloom and Barbaro, 1938). (This laudatory illustration pertains only to Wal-Mart’s environmental efforts because its responses regarding employee compensation and supplier relations have been more controversial.)

In the AMA Statement of Ethics, “stakeholders” are cited numerous times. First, various stakeholder groups are specifically mentioned in the preamble. Second, stakeholders are explicitly referenced regarding every endorsed ethical value except *fairness* and one could argue that they are implicit in the notion of fairness, since that concept embodies giving relevant parties what is their due. Third, in the Implementation section, all AMA members are encouraged to be courageous and proactive in dealing with relevant stakeholders.

ETHICAL MARKETERS SHOULD EMBRACE A PROCESS OF MORAL REASONING

The final BP lays out a series of steps that marketing managers should follow in making an ethical decision. The first stage is cultivating ethical awareness and sensitivity. This is the domain of corporate culture and is reinforced by management. Marketers must be able to “see” an ethical issue when it arises. Without a sense of awareness and sensitivity, marketers are less likely to be able to ascertain whether a certain decision contains ethical implications. In one of the most famous articles in the business ethics literature, *The Parable of the Sadhu* (1983), Buzz McCoy writes about his mountain climbing experience in the Himalayas and pens a classic line that illustrates this point: “Real moral dilemmas are ambiguous, and many of us hike right through them, unaware that they exist.”

The second step of the ethics decision-making protocol involves framing the ethical issue or question. It should be understood that the

formulation of an ethical question does not imply that the questionable practice will necessarily be deemed unethical (Laczniak and Murphy, 2006, p. 169). It is the role of the marketing manager to assist junior members of the department in ascertaining whether a potentially questionable policy such as “product placement” or “ambush marketing” constitutes an ethical issue that needs discussion and resolution.

Articulation of stakeholders affected by the marketing decision in question is the third stage of ethical decision-making process. Both primary and secondary stakeholders should be specified. For example, in a decision about whether to introduce a new and/or more violent update to a video game, prospective customers (both adult and underage), employees of the firm, and company stockholders should be considered. Game developers and retailers who might distribute the software are also important secondary stakeholders. Because of the software’s violent themes, both activist groups and society, in general, should be considered as well. If the company expects a potential public backlash, the secondary stakeholders and the fallout from the product launch needs to be addressed before moving forward.

The fourth step in the ethical reasoning process involves the selection of an ethical standard or standards. This could include simple maxims like the golden rule, the Wall Street Journal test or more complete ethical theories like utilitarianism, duty-based or virtue-based ethics. For example, the hypothetical decision of a local Ford dealer about whether to acquire a JB Byrider franchise should be evaluated using one or more of these standards. The Byrider franchise specializes in used automobiles that appeal to low to moderate income consumers. The past record of these franchises has been questioned because of the relatively high interest rates they charge and propensity to quickly repossess autos when customers fall behind on their payments (Grow and Epstein, 2007).

The fifth stage is “ethical analysis,” which involves applying the ethical standard to the ethical question keeping in mind the impact on impacted stakeholders. Continuing with the Byrider example, the auto dealer may believe that acquiring such a franchise will lead to more benefits for consumers than costs. Hence, using

a utilitarian analysis, the decision to go forward might be positive. However, with most other ethical standards, the decision might be called into question because this branded franchise has not historically operated with transparency toward consumers (a violation of virtue ethics); moreover, it appears that Byrider intends to sell cars to at least some consumers who cannot afford them (i.e., possibly failing to meet the duty-based ethical standard). The point of this example is that if a manager is a “principled” one, s/he will use multiple ethical criteria to evaluate decisions.

Sixth, a decision should be made using all the information gathered in the preceding stages. Usually, there are three options: acceptable to go forward; the strategy may be ethical if amended in some fashion; or practice should be abandoned. A positive example of where a company moved forward with a vetted decision, after a thorough ethical evaluation process, is BzzAgent. Here the organization, a buzz marketing agency, moved from instructing its agents to be “discreet” to the higher standard of disclosure – “you must tell people” – when asked if they were involved in instigating a “word-of-mouth” marketing campaign.

The final stage of the decision protocol is to monitor the outcomes of the “ethical” decision. Steps need to be taken so that unintended consequences do not occur such as inadvertently using ultrathin models in advertising, thereby contributing to perceptions of poor body image among young girls. The highly acclaimed Dove campaign showing women of “many sizes and shapes” was a positive response to the long-standing trend of only using slender models in cosmetics advertising. Similarly, marketers who sell to children and other vulnerable consumers have a special obligation to monitor the societal effects of their advertising and product usage. Studying the impact of marketing actions on stakeholders beyond consumers is the type of monitoring that one might expect of managers who exhibit moral imagination.

Although the AMA Statement of Ethics does not articulate its own set of steps for making ethical decisions, the entire document is aimed at helping marketers to become more aware of the ethical issues. In fact, the three central ethical norms – do no harm, foster trust in the

marketing system, and embrace ethical values – are helpful ethical guidelines that marketers can use in stage three and apply in stage four of the ethics assessment process. Finally, the six ethical values that embody the core of the AMA statement can be seen as an illustration of a “virtue ethics” approach to ethical issues.

CONCLUSION

Several conclusions can be drawn for marketing managers from the analysis of the seven BPs above. First, the marketing concept, strategy formulation, relationship marketing, and supply chain management are all inherently ethical activities. If any or all of these marketing practices are to be successful, a sense of trust and fairness must exist among marketers, their customers, suppliers, and end users of their products. This notion is implicit in the BPs. Clearly, the ethical dimensions of marketing are not new ideas but rather theory-inspired approaches that require renewed diligence.

Second, ethical issues facing marketers in the future will likely require both a normative and technical analysis. Most ethical problems are complex. One reaction by companies has been to hire ethics consultants or internal ethics officers to help them deal with these questions and set up ethics training programs. However, this is probably not enough any longer. For example, many environmental and solid-waste problems necessitate sophisticated technical advice on (for example) recycling versus landfill disposal. The “right” decision may not be clear until the scientific evidence is first factored in. Thus, both types of analyses should help illuminate the difficult choices ahead for marketing executives.

Third, marketing’s role in society and in dealing with social issues should be examined from an ethical standpoint. Marketing as a business practice has made major contributions to society over time and occasionally is judged harshly from an ethical performance viewpoint. But marketing can be an exceptional force for “good.” Marketing methods will increasingly be called upon to shape various social issues facing the world such as AIDS education, discouraging illegal drug use, helping publicize innovations in education, as well as various other social interventions that require promotion and

dissemination. Marketing has much to offer to the discussion and the potential alleviation of social problems; marketing-rooted strategy can contribute positively to environmental betterment and to meeting the needs of disadvantaged consumers in the future.

Fourth, ethical marketing companies exhibit a genuine stakeholder orientation and engagement. Exemplar companies, such as those profiled above, commit to represent all stakeholders because they recognize the rights, claims, and presumption that other affected parties expect of a business organization – especially recognitions that go beyond the basic requirements of the law. Our discussion of BP2 and BP6 directly illustrate this point. Although many firms list stakeholders as important in their website profiles, the most enlightened firms go the extra step in creating an ongoing dialogue with major stakeholders when changing conditions warrant such discussions.

Finally, ethical leadership is crucial for the success of any firm. While it starts with the CEO and CMO, other top-level marketing managers should also exhibit integrity and fairness in their dealings with employees and customers. While BP4 and BP7 both address the importance of managerial leadership, this idea pervades the very core of ethical marketing. The Implementation section of AMA Statement of Ethics calls on AMA members to be such leaders: “We expect AMA members to be courageous and proactive in leading and/or aiding their organizations in the fulfillment of the explicit and implicit promises made to those stakeholders.” Although we have concentrated on companies rather than individuals in providing profiles of enlightened and ethical marketing strategy, we want to conclude by noting the reflections of two ex-CEOs who have written persuasively on ethics and values-based leadership – Bill George and Sims (2007) and Harry Kraemer (2007).

In the end, the purpose of marketing strategy is to develop assets and competencies that create “value propositions” appreciated by the firm’s target markets on a sustained basis. The ethical perspectives discussed in the paragraphs above are both an articulation of how ethical marketing is conducted according to the highest professional ideals as well as a road map for the

cultivation of expanded consumer trust that accrues to organizations that embrace these approaches.

first-mover (pioneer) advantage

Peter N. Golder

First-mover (or pioneer) advantage is the long-term reward that may accrue to the first company to enter a new market (*see* PRODUCT CATEGORY). Five key theories underlie a potential first-mover advantage.

- *Ease of recall:* People recall more easily the first brand they use or hear about in a new product category. As a result, pioneering brands can remain top-of-mind, promoting word-of-mouth and ongoing purchases (*see* CONSUMER MEMORY PROCESSES).
- *Brand loyalty:* Consumers often develop a preference for purchasing brands that they have used previously (*see* PERCEPTION OF BRAND EQUITY; CONSUMER BRAND LOYALTY). By continuing to purchase the same brand, consumers avoid the cost of searching for alternative brands as well as the risk of possibly sampling a poor brand. In new product categories, brand loyalty can have especially strong effects because first movers shape the expectations of the entire category. Essentially, first movers are prototypes against which later entrants are judged. First movers determine which attributes are important and which levels of attributes are appropriate. Thus, later entrants may be perceived as inferior to the standard set by the pioneer or be perceived as “me-too” copies of the original brand.
- *Technological leadership:* Pioneers can operate at the technological frontier of the new-product category. As a result, they have the opportunity to secure patents that may deter other firms from entering a category or at least inhibit their ability to compete (*see* INNOVATION TYPOLOGIES; INTELLECTUAL PROPERTY RIGHTS).
- *Economies of scale and experience:* First movers can be the first firm to achieve substantial volume in manufacturing and sales. This volume can result in lower costs and the associated experience may lead to higher quality and better features than the competitors’ products.
- *Resource capture:* First movers have the opportunity to secure the best raw materials, suppliers, consumer segments, and distribution outlets (*see* MARKETING CHANNEL STRATEGY). Later entrants may be left with less profitable alternatives. For example, first movers can sell to innovators, who are eager to purchase new products, while later entrants are left trying to sell to noninnovators. In addition, first movers may develop broader product lines enabling them to appeal to a variety of market segments.

Many empirical studies report results that support a first-mover advantage on several key performance measures. First, they report an average MARKET SHARE for first movers of approximately 30%. Second, one contributing factor to this high market share is that remarkably few pioneers fail. However, early empirical studies do not report a specific failure rate. Third, first movers’ high market shares result in the finding that most market leaders are first movers. Finally, studies report that market leaders tend to remain market leaders for many years, often decades.

Subsequent research has found that two key limitations result in first movers having substantially lower rewards than described above (*see* LATER MOVER (NONPIONEER) ADVANTAGE for more details). The first limitation is that initial studies include only surviving brands in a category. Therefore, the longest surviving brand may have been successful for a variety of reasons other than being the first mover. The second limitation in many studies is that companies classified themselves as either first movers or later entrants (*see* MARKET DEFINITION; SURVEY RESEARCH). As a result, successful firms were more likely to attribute their success to being a first mover on some aspect of their strategy even though earlier entrants employing inferior strategies may have failed.

The diminished rewards for first movers identified in later studies have led to a reconsideration of first movers’ theoretical advantages. All of these theories rely on the presumption that the first mover was successful on one or more important dimensions. That is, the first mover offered a superior product, positioned it properly to the most attractive

2 first-mover (pioneer) advantage

market segment, locked up the most attractive distribution channel, and continued to benefit by staying at the forefronts of technology and experience. Some first movers are able to do these things, but most are not. As a result, companies seeking to establish a first-mover advantage would be wise to regard the situation as a first-mover opportunity instead. Long-term success will result from assiduously cultivating these opportunities over time.

global marketing strategy

Johnny K. Johansson

INTRODUCTION

A global marketing strategy (GMS) is a strategy that encompasses countries from several different regions in the world and aims at coordinating a company's marketing efforts in markets in these countries.

A GMS does not necessarily cover all countries but it should apply across several regions. A typical regional breakdown is as follows: Africa, Asia, and the Pacific (including Australia) Europe and the Middle East, Latin America, and North America. A "regional" marketing strategy is one that coordinates the marketing effort in one region.

A GMS should not be confused with a global production strategy. Outsourcing and foreign manufacturing subsidiaries, common features of a global production strategy, can be used with or without a GMS for the finished products.

As listed in Table 1, GMSs can involve one or more of several activities.

The coordination involved in implementing a GMS unavoidably leads to a certain level of uniformity of branding, of packaging, of promotional appeal, and so on (Zou and Cavusgil, 2002). This also means that a GMS, in some ways, goes counter to a true customer orientation (see MARKETING PLANNING). The product and marketing mix are not adapted to local preferences, as a customer orientation suggests. This is a potential weakness of GMSs,

and leaves opportunities open for local products and brands.

As the notion of integrated marketing communications (see INTEGRATED MARKETING COMMUNICATION STRATEGY) suggests, the ensuing consistency can have positive revenue benefits because of reinforcement of a unique message, spillovers between countries, and so on. But the main driving force behind the adoption of a GMS is the scale and scope of cost advantages from such uniform marketing strategies. These cost advantages include elimination of unnecessary duplication of effort, savings on multilingual and same-size packaging, use of the same promotional material, quantity discounts when buying media, and so on. The pros and cons of a GMS are given in Table 2.

THE ORGANIZATIONAL CONTEXT

Firms typically contemplate adopting a more coordinated GMS, once they have significant presence in several countries and regions. Since local markets will never be exactly the same, a proposed global strategy will generally not be welcomed by the country managers. The existing local operations will have to be convinced to adopt the new global strategy. Thus, a GMS is always top-down, not bottom-up, and it is easy for antiglobalization sentiments to stir even within a multinational company.

The typical solution to this problem is to allow country managers to be involved in the formulation of the GMS, and to form cross-national teams to participate in the implementation. It is also common to designate one country the "lead" market for the strategy, and use its current strategy as a starting point for the global strategy. This lead country is typically one of the larger markets and one where the firm has a strong market share. In multibrand firms, it is also common to limit a global strategy to one or two brands, allowing the local subsidiaries to keep control of some of their own brands.

GLOBAL SEGMENTATION AND POSITIONING

The firms most likely to engage in GMSs are those present in global markets. Global markets are those where customer needs, wants,

Table 1 Components of a global marketing strategy.

Items Listed in Order of Descending Occurrence

- Identical brand names
- Uniform packaging
- Standardized products
- Similar advertising messages
- Coordinated pricing
- Synchronized product introductions
- Coordinated sales campaigns

Table 2 General pros and cons of global marketing strategies.

| | <i>Pros</i> | <i>Cons</i> |
|----------------|---|---|
| ● Revenue side | Reinforced message, unique idea Spillover of brand awareness Enhanced liking (mere exposure) | Culturally insensitive Antiglobal target Vulnerable to gray trade |
| ● Cost side | Reduces duplication, waste Uniform product design, packaging, advertising Quantity discounts in media buy | Requires managerial time Lowers morale in subsidiaries, agencies |

and preferences are quite similar across the globe (*see* MARKET DEFINITION). Typical product categories are technology products, including consumer electronics, cameras and computers, branded luxury products, and also apparel, personal care, and entertainment categories where, for certain segments, globally standardized products are desired by all. By contrast, in multidomestic markets such as food and drink, where preferences are more culturally determined, global coordination is less common (*see* CUSTOMER ANALYSIS). For example, ACNielsen's cross-national data suggest there are only 43 global brands in the consumer packaged goods categories found in the typical supermarket (ACNielsen, 2001).

Global segmentation. The need to target similar segments in different countries is an attempt to minimize the drawbacks of a coordinated global strategy (*see* MARKET SEGMENTATION AND TARGETING). A typical cross-national segment targeted with a standardized product is the teenage and young adult segments, where preferences are allegedly very similar even for food and drink categories. Coca Cola uses the same one-word slogan "Always" around the world. Nike is positioned with a rebellious image in many countries, even though the particular sports associated with Nike differ by country. Technology brands such as the iPod have usually even more coordinated global strategies, with synchronized rollouts of new models across countries.

Global marketers might use a two-stage approach to market segmentation (*see* MARKET SEGMENTATION AND TARGETING), first grouping countries into similar regions to

increase the chances of finding homogeneous subgroups within each region. Often the first step amounts to selecting a trade bloc, such as the European Union. As research has documented, many global strategies are, in fact, more regional than global (Rugman, 2005).

A GMS can also be successful if the firm has managed to change local preferences. A new product entering a local market will usually change preferences to some degree, whether by new features, promotion, or price. This is the basis for the extreme standardization proposed by Levitt in his seminal 1983 HBR (Harvard Business Review) article, where he suggests that "everybody" likes the same products. Examples of this abound. IKEA, the Swedish furniture retailer, has changed the market for furniture in many countries – it uses a very standardized and coordinated marketing strategy, focusing around its simple and functional furniture, annual catalog, and warehouse stores. Starbucks, the American coffee chain, also has re-created and enlarged a mature market in several countries with its new coffee choices, novel store layouts, and wider menu. In other cases, changes in the environment have affected preferences so as to make standardization possible. "Green" products are naturally targeting global segments, as are the lighter beers, the bottled waters, and the shift to wines. Such global segments naturally induce companies to adopt GMSs.

Global positioning. The main issue in global positioning (*see* POSITIONING ANALYSIS AND STRATEGIES) is whether the product offering should be positioned the same way everywhere or not. Complicating the issue is the fact that even with complete uniformity of the marketing mix,

the arrived-at position may still differ between countries. A classic example are Levi's jeans, whose rugged outdoors image places it in a mainstream American lifestyle segment, but becomes a stylish icon in other countries. Also, as this example illustrates, even if a brand wants to be seen as "global," its position is typically affected positively or negatively by its country of origin.

A fundamental factor affecting transferability of a position is the actual use of the product. A food product such as apples might be consumed as a healthy snack in the West ("An apple a day keeps the doctor away" as the saying goes). But in Japan, apples are a favorite item in the gift-giving season, placing a premium on color, packaging, and price – hardly the same positioning.

Even without such dramatic usage differences, differences in economic development and cultural distance, in general, are main factors influencing the potential for an identical position. A Ford car may be positioned as a functional value product in Europe, but might be a status symbol in a poor country. First-time buyers in emerging markets rarely view products the same way as buyers in the more mature markets, where preferences are well established. For example, the successful Buicks offered to new customers in China offer quite different benefits from those offered Buick customers in the United States, even though the product is largely the same.

The strength of local competition (*see* COMPETITIVE ANALYSIS) is also likely to vary across countries, affecting the positioning. Where domestic competitors are strong, a foreign brand that is a mainstream brand at home will typically attempt to target a niche abroad. This applies to many European brands including Heineken, Illycaffe, and Volvo. In other cases, a company with a niche position at home may target a more mainstream position in another market – an example is Japanese Honda in the US auto market. In global markets, where often the same global players compete in the major foreign markets, positioning is more likely to remain constant across the mature markets. Examples include automobiles, with the global players occupying very similar positions in most markets. This is less true for new product categories that are still in the growth stage in many countries and the brands are not equally well known everywhere. Cell phone makers

Nokia, Samsung, and Sony-Ericsson occupy quite different positions in each market.

The stage of the life cycle (*see* STAGES OF THE PRODUCT LIFE CYCLE) is also likely to vary across countries, affecting how well a particular position can be transferred. In the early stages, with preferences still in flux, a strategy based on the positioning in a lead country may not be very effective in a new country. Thus, the first automatic single-lens reflex camera was introduced by Canon as a mainstream product in Japan, but a specialty product for more professional photography overseas. In emerging countries with their pent-up demand, however, even new consumers aspire for the best products in the leading markets. This is why some Western companies (such as Electrolux, the home appliance manufacturer) will position themselves at the top of the market even in a country like Russia.

The typical strategic assumption is that a globally uniform positioning requires similarity of culture, of competition, and of life cycle stage. However, even in countries where one or more of these requirements are not met, a standardized global positioning may still work. For example, when global communications have made the brand name already well known, a global strategy may work even in a multidomestic market. McDonald's successful entry into many emerging markets is a case in point. And even where domestic competition is strong and would suggest a niche positioning, external events may shift the market in favor of a newcomer. This happened, for example, when the Japanese autos entered the American market and gained strength during the 1970s oil crisis. But these are exceptions and are certainly not automatic, as Coca Cola learned in India when local ThumsUp rebounded (*see* the section Global Brands).

THE GLOBAL MARKETING MIX

Global products and services. Standardization of the product or service is usually a major feature of a global MARKETING MIX. "Product Standardization" means uniformity of product or service features, design, and styling. There are several advantages to such standardization, including those listed in Table 3.

Table 3 Advantages of product standardization.

-
- Cost reduction
 - Improved quality
 - Enhanced customer preference
-

The advantages are mainly on the cost side – scale economies from the larger number of identical units produced. But there are also quality advantages involved. With longer series, there is more reason to invest in specialized technology, machine tools, components, and parts, yielding higher and more consistent quality. Finally, there is a possible positive demand effect on customers. Because of the prevalence of the products and designs, the “mere exposure” of individuals to the products engenders a positive impact on preferences. This is an effect which partly depends on competitive imitation – when most cell phones feature a built-in camera, consumers “want” a camera with their cell phone (see COMPETITIVE ANALYSIS).

The disadvantages of product standardization are mainly on the demand side (see Table 4).

Apart from the case of pent-up demand in an emerging country, standardized products rarely manage to target precisely a specific segment in a new country market. They are at least slightly off target. This is not always such an obstacle to success. First, preferences may change – the standardized product may offer features not offered before in that market. Honda’s 1970s entry into the US car market exemplifies this case, with the car offering both fuel efficiency and sportiness. Second, a mispositioning may be overcome by a strong brand name. The McDonald’s entries in emerging markets fall in this category. Third, the entering product may well be sold at a low price – its scale advantages can allow such a strategy. This was the strategy followed by Samsung before its later drive toward a strong global brand (Quelch and Harrington, 2004).

Since the typical multinational company does manufacturing in a large number of country subsidiaries, the need for scale has sometimes made it necessary to designate local production sites as suppliers for the whole world. Toyota’s Kentucky plant produces the Camry for global

Table 4 Disadvantages of product standardization.

-
- Off-target
 - Lack of uniqueness
-

distribution. The BMW Z4 sports car is only produced in South Carolina. Apple computers are all produced in Taiwan. In general, however, the risks of local strikes and political conflict make most companies assign production to more than one site.

From a marketing perspective, a uniform product or service is often less acceptable locally. Of course, some localization is always necessary in any case – electric appliances face different voltages and plugs, safety regulations differ between countries, and homologation requirements differ. But the more critical issues revolve around customer acceptance. What is seen as a good product or service in one market might not be acceptable elsewhere.

The fact is that there are relatively few products and services that are identical around the world. One would expect that products in global markets, such as technology products, would be identical. But generally speaking, PCs and cell phones are smaller in Asia, automobiles have a harder suspension in Europe than in the United States, and even stereo speakers vary slightly in bass level between North America (heavy on bass) and Asia (where smaller apartments places the listener closer). The classic failure by Euro Disney to transfer its American theme park unchanged to France is a good example of misguided standardization of a service product. Despite the success of the strategy in Tokyo, the Euro effort fell flat for many reasons, one of which was the no-alcohol rule inimical to Continental Europeans.

Luxury products are usually the same across the globe, and utilitarian items such as automobile tires, toothpaste, and kitchen utensils can be standardized. But products such as shampoos, soaps, and personal-care items need to take account of hair types, skin color, and water quality to perform satisfactorily. Coca Cola’s level of sweetness differs across countries, McDonald’s menu is adapted to country

preferences (partly to reduce antiglobalization protests), and apparel manufacturers have to make adjustments for different body proportions between Western and Asian peoples.

To deal with these adaptations while trying to retain some scale economies, companies resort to two solutions. One solution is to use the same basic design or “platform” for the product, and then adapt by adding alternative features at the later stage of manufacturing. This is common in automobiles, where the platform involves the chassis on which the body is then fitted. But the concept is also used in the manufacturing of electronic products, computers, and home appliances. This is the solution adopted by Coca Cola and McDonald’s as well.

A second related option is to break up the product into component modules that can be produced in large series to gain the scale advantages, and then produce different products by different combinations of modules. This has become a very prominent manufacturing strategy for large companies, since it allows the different modules to be outsourced and offshored. The manufacturing process then becomes a simple assembly process, which can then be done locally, if necessary, to gain lower tariff rates. This allows the company to “mix and match” features for different country markets, which helps adaptation to local preferences. It also helps to make the products in different markets somewhat different, helping to limit gray trade (more on gray trade below).

In the end, companies do not need to offer identical products everywhere in order to gain the scale economies of product standardization. Thus, a company can develop a coordinated global strategy even without a completely standardized product. But it is almost impossible to develop a GMS without a strong global brand.

Global brands. Keeping the same brand name everywhere has become the signature feature of a global marketer, and “global branding” has become an obsession among many multinationals. For example, the Interbrew (now InBev) company’s analysis of the Heineken advantage in profitability draws the conclusion that it is the lack of a global brand that depresses its own bottom-line performance. Hence, top management has decreed that Stella Artois be

Interbrew’s global “flagship” brand (Beamish and Goerzen, 2000).

Three definitions follow:

- *Global brands* are brands that are well known and recognized in all major markets of the world. (e.g., Sony, Mercedes-Benz, Microsoft, Nokia).
- *Regional brands* are brands that are the same across a region (e.g., P&G’s Ariel in Europe is Tide elsewhere; Acura is Honda Legend in Asia).
- *Local brands* are brands found in only one or two markets (e.g., Suntory whisky in Japan, A&W root beer in the United States, and the Trabant car in former East Germany).

Strictly speaking, the brand may be global although the product is not available everywhere – as happens to be the case for Rolls Royce as well as for Coca Cola. This usually means there may be a pent-up demand for some global brands, as was seen when McDonald’s entered Russia in the 1990s.

Global brands have received increased attention from top management in many multinationals because of the importance of brand equity as a financial asset (*see PERCEPTION OF BRAND EQUITY*). Expanding into new markets is an obvious way of building further financial equity, which is usually calculated by simply aggregating projected revenues across country markets. Not surprisingly, most top brands in terms of financial equity are global. But a strong brand not only needs reach across countries, it also needs allegiance from local customers. As global brands have stretched further to build financial equity, local brands have been able to defend their turf by staying closer to their customer and building affinity, or what may be called *soft equity* (*see CUSTOMER EQUITY*).

Recognizing this, many global companies not only market their global brand in a country market but might also buy up a successful local brand and retain its brand name – and customers. One example is Coca Cola in India. After its reentry in 1993 (Coca Cola had exited India in 1977 instead of giving up its secret formula), Coca Cola acquired ThumsUp, a leading local producer, with the idea of replacing its brand

with Coca Cola. But after several efforts at withdrawing ThumsUp and launching its own brand, Coca Cola finally gave up and shifted marketing resources to ThumsUp. The problem was that Coca Cola was positioning itself as the young teenage drink, just as it had done in many countries, while in India, where alcohol consumption is very limited for religious and cultural reasons, the main cola market was among young adults who in other parts of the world were drinking beer. ThumsUp in India is a rebel's drink, hardly the image of Coca Cola.

The most clear-cut advantages of global brands are the cost efficiencies from scale and scope. The typical benefits to global brands are several (see Table 5).

The cost efficiencies tend to come from the ability to produce identical products and packaging in long series, and also because global brands can draw on uniform global promotions (more on this below). Demand spillover is a result of the increased exposure to the same brand in many places, especially useful when customers are global. The growth of international tourism has been a strong driver of global brands. The status and esteem advantages have been shown by researchers, especially prominent in less-developed countries. While some research has demonstrated a high quality perception for global brands, the more firmly established finding is that global brands tend to have a more consistent quality than local brands.

The disadvantages of global brands become advantages for local brands. Local brands can usually count on the advantages in Table 6.

Of course, none of these advantages come without effort and disciplined application by the firms, whether global or local. The arrival of global brands into many markets has been a challenge for many local brands who think that local consumers will automatically stay loyal.

Table 5 Benefits to global brands.

- Scale and scope economies
- Demand spillover
- Global customers
- High esteem, status
- Consistent quality

Table 6 Advantages for local brands.

- Local brand affinity
- Motivated local employees
- Prodomestic (and Antiglobalization) sentiment

Global brands, as Naomi Klein claims, have changed the playing field – but they have not, as she claims, simply dominated local brands (Klein, 2002).

Global pricing and distribution. In GMSs, pricing, and distribution are more closely connected than at home. The reason is not that the costs involved in distribution (transportation but also insurance and custom duties) necessarily raise the final price to the customer. Such straight “price escalation” does not usually occur except in one-time transactions. Many multinationals have strong home market “cash cows,” and when faced with more intense competition in foreign markets they reduce prices by lowering transfer prices to their subsidiaries. Some firms also use foreign markets as an easy way out of overcapacity, applying marginal cost pricing procedures (although these can run afoul of dumping laws). And the improved efficiency of global transportation, thanks to global express carriers and consolidated shipment procedures, means that geographic distance is no longer the trade barrier it once was. Transportation costs are typically a small proportion of the total price paid (see MARKETING CHANNEL STRATEGY).

The strong connection between pricing and distribution rests more directly on another phenomenon. The ease of transportation, coupled with differing local prices and currency fluctuations, are what provide the margin that allows for arbitrage opportunities for customers to buy branded products cheaper abroad. This is an instance of so-called “gray trade” – the importation of branded products through other than authorized channels (see MULTICHANNEL MARKETING). It is the rise of gray trade that force multinationals to decide pricing and distribution strategies jointly – and even multinationals that would otherwise not contemplate a global strategy, have to find a way to align prices to avoid such trade.

Gray trade affects a number of multinationals. For example, there are numerous stories of Asian contract manufacturers who make branded products for Western multinationals on day shifts, and then produce an added batch of identical products on the night shift. These products are then shipped abroad at low costs, distributed via indirect channels perhaps from a third country, and finally appear on the various markets in the West. In other cases, gray trade involves Western distributors (large European retailers, for example) who acquire goods in a low-priced country and then sell it at higher prices at home. Britain's Tesco chain sent buyers to Wal-Mart stores in the United States to buy Levi's for resale at home, a practice that was stopped by a European court. Another popular form of gray trade, "shopping tourism," is what happens when overseas trips are arranged for tourists to buy products cheaper in a foreign country.

The drivers of gray trade include the factors in Table 7.

Gray trade is not usually illegal. By contrast, trade in counterfeits (fake products) is illegal and vigorously opposed by multinationals that fear the loss of revenue and dilution of their brand name. But there are similar negative effects from gray trade as from counterfeits. Gray trade strains the relationship with authorized channel members since channel members face intrabrand competition. There may be legal liabilities, usually involving warranties that cannot be honored. There is also a risk of erosion of brand equity because of the lower price in the market. Seiko, the Japanese watch maker, has failed to establish itself as a strong premium brand partly for this reason. And gray trade complicates global coordination when one country realizes a sudden influx of gray goods. Even though companies cannot take legal action, when faced with gray trade, they have to engage

in relationship building with distributors, screen orders carefully, and monitor shipments.

Because of pricing regulations, the multinational producer cannot usually dictate retail prices in local markets (see PRICING STRATEGY). Nevertheless, to achieve the desired brand position, they can use suggested retail prices. These are the prices that have to be coordinated across countries because customers can purchase the products anywhere in the world. But to coordinate prices is difficult, for several reasons as shown in Table 8.

One single global price is unrealistic. Even though a business-to-business company such as Boeing, the aircraft builder, quotes all its prices in American dollars, exchange rate problems still arise for its customers. For many global companies, the solution is to devise "pricing corridors," centered around a desired positioning price. The "corridors" are the limits of prices between which the local price may vary without interference from headquarters. The price corridors should reflect not only demand and competitive pressure in the local market but also the differences in exchange rates and likelihood of gray distribution – a very difficult balancing act. In addition to formal corridors with a centralized positioning price, the global pricing coordination typically involves informal coordination with the local subsidiary to allow flexibility (Assmus and Wiese, 1995).

Global marketing communications. Next to global brands, the most visible aspect of a GMS is perhaps global advertising. *Global advertising* can be defined as media advertising that is more or less uniform across many countries, often, but not necessarily, in media vehicles with global reach. Although global appeals had been used previously in promotions – IBM's

Table 7 Selected drivers of "gray trade."

- Transportation is global and efficient
- Trade barriers are low
- Products and brands are standardized
- Communication is global

Table 8 Why global coordination of prices is difficult.

- Currency exchange rates fluctuate
- Local distributors are independent
- Import prices to subsidiaries have to consider tariffs, taxes.
- Local competition varies across countries

Table 9 Major drivers of global advertising.

Supply Side

- Global ad agencies
- Global media

Demand Side

- Global customers
- Preference convergence

global “Think” slogan appeared as early as the 1920s – global advertising arrived with the advertising agency Saatchi & Saatchi’s television commercial “Manhattan Landing” for British Airways in the early 1980s. With increasing globalization and the stress on global brands, the momentum behind global advertising has been sustained despite antiglobalization and prolocalization sentiments around the globe. One contributing factor has been the rise of the Internet and the availability of many commercials on sites such as YouTube, where even local advertisement campaigns potentially have global reach.

There are several forces behind the need for integrated global communications (see INTEGRATED MARKETING COMMUNICATION STRATEGY). One can distinguish between supply-side drivers and demand-side drivers, as shown in Table 9.

On the supply side, the emergence of consolidated global advertisement agencies has played a significant role in generating more global advertising. Although in many ways, the agency globalization has been a response to the globalization of the client firms – global managers find it useful to deal with the same agency in different parts of the world – once established, the global agency will naturally want to leverage its global capabilities (as in the Saatchi & Saatchi case). The global agency can also claim superior production values with a global campaign, since more resources can be used for one television commercial that is going to be shown around the world. The emergence of global media – the BBC, the Sky channel, the CNN, Financial Times, and so on – and their consolidation into global media companies such as Viacom, Bertelsmann, and Time Warner has also encouraged the

development of global advertising and promotions that can be used effectively everywhere. There are cost savings in buying all media from one consolidated source.

On the demand side, customers are increasingly global. Consumers now travel much more than before as the lower cost of travel have made for many more tourists, and for business-to-business products, the customers are often multinational companies. In addition, with global communication producing spillovers between countries, local preferences change and allow the penetration of global brands in local markets using standardized appeals. Globally coordinated advertising thus becomes a natural complement to the global brand. It has given us the “Always” of Coca Cola, the “Our Passion” of Microsoft, the “Do you dream Sony?” and “The Ultimate Driving Machine” of BMW. Global Internet ads are now common, with companies such as IBM and Heineken producing commercials on their Web home pages and repeated on the YouTube.

In the general case, however, not all the marketing communications of a global company is globally coordinated. First of all, media advertising is only one of several promotional tools. Many retail promotions such as POP (point of purchase), coupons, and free samples, are necessarily more localized. Regulations vary across countries. Not all countries’ retail regulations allow contests, for example, and in many cases, coupon redemptions are denied by stores. Even naturally global promotions such as sponsorships of the Olympics and the World Cup often require local input to leverage the promotion effectively. In one notorious instance, Budweiser’s sponsorship of the World Cup in Germany in 2006 encountered opposition from German brewers and consumers. In an effort to appease German drinkers, Budweiser made a local deal to allow the German-made Bitburger beer to be sold in stadiums, albeit in unmarked cups.

But even media advertising is rarely fully globalized. The motivation for local subsidiaries and their agencies to do their best creative work is enhanced with more autonomy. Not all media are equally available in all countries, and the costs vary considerably. Effectiveness also varies. In poorer countries, print media are usually less effective. By contrast, Europe on the whole

gives much greater weight to print than other countries. The Internet, a new and naturally global channel of communications, has still not penetrated all corners of the world.

In addition, the advertising message often has to be adapted. Linguistic, cultural, and religious differences can prevent standardization of advertising messages and render symbols inappropriate. IKEA's use of the Moose, successful in Europe and Canada, was too provincial in the United States, where a simpler blue-and-yellow logo is used. Product usage may not be the same, making a uniform appeal miss the target. Ice cream is bought for its nutritional value in poorer countries, not so in advanced markets. This means the local subsidiary and its advertising agency usually have to do more than merely translate a message. Not all local adaptations work of course. A Nike advertisement with LeBron James, the American athlete, slaying a dragon turned out to be a failed local adaptation in China, where dragons are a force for good.

Because of these issues, most companies dedicate only a portion of their total advertising budget to a global campaign. An example comes from Samsung, the Korean electronics maker who has moved ahead of Sony in global brand value in the last few years (*see* BRAND VALUE). In 2003 about 40% of above-the-line budgeting was for global advertising. The remaining 60% of a \$1 billion budget was allocated to local and regional subsidiaries for their nonglobal spending on specific products and markets. While the localized campaigns may employ local agencies, it is common for the global campaign to be handled by one large global agency, FCB (Foote, Cone, and Belding), in the Samsung case.

Most global companies place strict limits on how their name should be portrayed, including fonts and coloring. Sony requires all uses of their name and logo to be approved at headquarters in Tokyo before release. There are a few identical ads used, particularly in print advertising. The Marlboro cowboy can be seen around the world. The well known Absolut advertisements, with the shape of the bottle contoured in the advertisement, are used in many countries, sometimes localized. These are examples of the notion that

a great idea can be used everywhere, a common assertion in advertising circles.

But even in a global campaign there is usually some variety. The typical form of global advertising in television follows what is known as pattern standardization. Here the advertisement visualization is adapted to local culture and language, with recognizable local spokespersons and actors, and a story that has local appeal. The brand name and logo are identical, and the final slogan is usually translated directly. Instead of actors speaking, voiceovers allow local language to be superimposed on a commercial. In this form, global advertising is becoming more common today, creating a unified image of corporations and brands as well as countries and places.

Summarizing, the advantages of global communications include those shown in Table 10. The potential disadvantages are also several, as shown in Table 11.

In the end, most companies play it safe, with some global uniformity but allocating the majority of the funds for regional and local adaptation of communications.

CONCLUSION

GMSs have become increasingly important with the internationalization of business and

Table 10 Advantages of integrated global communications.

- Consistency of brand communications
- Media spillover
- Cost savings
- Improved production
- Leveraging a great idea

Table 11 The disadvantages of integrated global communications.

- Images and symbols might not be locally acceptable
- Appropriate media might not be available
- Product usage is not the same
- Local creativity can be stifled

globalization of markets. Even though they are characterized by centralized coordination and streamlining to achieve scale and scope economies, localization, and adaptation are becoming increasingly important as emerging markets rapidly manifest culturally and ethnically differentiated consumer demand. Global success depends crucially on striking the right balance between uniformity and local adaptation. This balance, as we have seen, involves both top-down leadership and sensitivity to local markets – a true managerial challenge.

go-to-market strategy

Raji Srinivasan

The firm's go-to-market strategy involves the development of a marketing program to create, capture, and sustain value with the firm's offering for the firm's customers, given that the firm has identified a product to market.

Typically, the firm's go-to-market strategy can be conceptualized into two stages: (i) market segmentation, target market selection and positioning, given the product's (good or service) unique selling proposition, (ii) the marketing mix for the product, given the market segment the firm seeks to target for the product. These two stages in the firm's go-to-market strategy are discussed below.

MARKET SEGMENTATION, TARGET MARKET SELECTION, AND POSITIONING

The centerpiece of the firm's go-to-market strategy is the customer. The firm must identify the customers it seeks to address with the product on hand. The appropriate identification of the target market is a prerequisite for the development of a successful go-to-market strategy, allowing the firm to focus its marketing efforts on the appropriate customer segments.

Market segmentation calls for dividing the market into groups of customers, market segments, each with distinct characteristics (e.g., demographics, psychographics, behaviors, lifestyles). The objective of market segmentation is to develop groups of customers who substantially differ from each other, but are homogenous within the group (Rao and Steckel, 1998). Segmentation requires the following three steps from the marketer: (i) they understand customers' needs and the benefits that customers seek from the product, (ii) segment the market and develop prototypical customer profiles either based on customer demographics and/or benefits sought, and (iii) identify the observable variables (e.g., demographic characteristics) most likely to be discriminatory among the different customer segments.

Target market selection involves evaluating each market segment's attractiveness and the identification of one or more segments to enter.

In addition to the identification of the market segment, the marketer must also have insights on their firm's strengths (and weaknesses) and that of their competitors. The objective of target market selection is to identify target markets that are most profitable, given the product's features and benefits, costs of entering the market, and the market segment's characteristics. The crucial step in target market selection is a differential advantage analysis, an understanding of the firm's offerings, relative to the competitors' offerings. In addition to an understanding of competitors' offerings, it is also useful to anticipate competitive reactions so that such reactions can be incorporated into the development of the marketing program for the product.

Positioning is defined as the marketer's effort to identify a unique selling proposition for the product, so that the product occupies a clear, distinctive, and attractive position relative to competing products in the minds of target customers (Ries and Trout, 1981). A good positioning statement should address the following three questions: Who are the customers? What is the set of needs that the product fulfills? Why is the product the best option to satisfy those needs? A good positioning statement is aimed at potential customers, reflects clear differentiation of the product from competitive offerings, and guides the development of the marketing plan for the product.

MARKETING MIX

The firm's *marketing mix* describes the set of activities comprising a firm's marketing program (Borden, 1964). Borden specified twelve marketing mix elements: product planning/merchandising, pricing, brandings, distribution channel, personal selling, advertising, promotions, packaging, display, servicing, physical handling, and market research. Over time, these 12 elements have been considered as the four Ps – product, place, promotion, and price.

Product decisions involve aspects of the product which include the physical features of the product, brand name, and financing plans (Crawford, 1997). A broad conceptualization of product is the key to achieve effective differentiation from competitors' offerings. Product decisions also involve considerations

2 go-to-market strategy

of product line length (how many products to cover different market segments?) and product line depth (how many types of a given product?)

Place decisions refer to decisions about the firm's distribution channels or how the firm "goes to market." A customer-behavior-driven approach to channel design is advocated to ensure that customers' needs are met in the most cost-efficient manner (Stern, El-Ansary, and Coughlan, 1996). An important issue with respect to channel design is that the firm should not only decide which types of channels to employ (distributors, retailers, jobbers) but also determine the functions and the appropriate channel incentive design for the different channel members. A key aspect of channel design is the identification of policies and procedures that will be used to ensure that the various members in the channel perform their designated functions.

Promotion decisions refer to the set of ways in which the firm communicates with its customers with a view to increase awareness of the product, and persuading customers to either try the product or repeat purchase it. Effective marketing for a product requires an integrated marketing communications plan combining personal selling efforts and impersonal approaches including advertising, sales promotion, and public relations (Aaker, Batra, and Myers, 1992). A key to developing an effective communications program is to understand the people involved in the decision-making process, and their motivations and needs. In today's environment with the World Wide Web playing an important role in consumers' purchase decisions, the role of user-generated content including consumer blogs and ratings are proving to be as influential in consumer decision making as firm-provided information.

Price decisions refer to decisions about the product's pricing. Typically, when the product, place, and promotion are decided upon, the

consumer's perception of value of the product is determined, so that the price range of the product may be in place. There may be several considerations that guide pricing decisions such as the cost of the product, which includes manufacturing, promotion, and distribution costs, cost structure, competitors' pricing in the market, consumers' price elasticities, the availability of substitutes for the product, the firm's profit objectives, the firm's market objectives, and so on (Dolan and Simon, 1996).

An effective go-to-market strategy is both an art and a science that involves the integration of customer insights and analytics to ensure that there is a match between the firm's target market and the marketing mix developed for the product so that both consumer needs and the firm's performance objectives are met.

innovation diffusion

Vijay Mahajan

The diffusion of innovation is defined as the process by which that innovation is communicated through certain channels over time among the members of a social system (Rogers, 1995). The diffusion process consists of four key elements: innovation, communication channels, time, and the social system.

As a theory of communication, diffusion theory's main focus is on communication channels, which are means by which information about an innovation is transmitted to or within the social system. It consists of both the mass media and interpersonal communications. Members of a social system have different propensities for relying on mass media or interpersonal channels when seeking information about an innovation. Interpersonal communications, including nonverbal observations, are important influences in determining the speed and shape of the diffusion process in a social system.

Recent literature suggests two additional mechanisms for innovation diffusion: signals and network externalities (Peres, Mahajan and Muller, 2009). Signals are defined as any market information other than personal recommendation that can be used by a potential adopter to make an adoption decision (e.g., the number of previous adopters may signal better product quality). Network externality refers to the observation that the utility of some products or services may increase as more consumers adopt the new product (e.g., Internet or mobile phones).

Consumer behavior researchers in marketing have focused on developing and evaluating hypotheses related to the adoption and diffusion process. For example, how do the innovation attributes (e.g., complexity) affect the adoption/diffusion process? What are the differences between the various adopter categories (e.g., innovators vs laggards)? How does the negative and positive word-of-mouth affect the diffusion speed? What is the role of opinion leaders in the diffusion process?

The marketing management literature has focused on the implications of the above

hypotheses for targeting and developing marketing strategies aimed at potential adopters. For example, how should a new product be positioned for innovators versus laggards? When might it be possible to skip the innovators and directly go to the mass market? What is the relationship between sampling and the diffusion speed?

Researchers in marketing science have contributed to the development of diffusion theory by suggesting analytical models that describe and forecast the diffusion of an innovation in a social system. Among these models, the best known is the Bass model (Bass, 1969). This model assumes that the potential adopters comprise of two groups. The first group is influenced only by the mass media-communication and is termed as "innovators." The second group is influenced only by the word-of-mouth communication and is termed as "imitators." Since its publication, a number of applications, estimation procedures, and extensions have been reported incorporating the effect of marketing mix variables, competition to study the diffusion of the various brands and their influence on each other's growth, and diffusion over markets and countries (spatial diffusion) (Mahajan, Muller and Wind, 2000). The Bass model yields a unimodal (single peak) curve for the incremental adoptions over time and an S-shaped curve for the cumulative adoptions over time. The recent studies suggest that the Bass curve should include three other elements or turning points: take-off, saddle, and technological substitution.

The Bass model starts with the adoption of an initial group of adopters, yet does not provide explanations as to the mechanisms that led to this adoption. Following take-off, the Bass model predicts a monotonic increase in sales. However, in some markets, this increase might be nonmonotonic, and a sudden decrease in adoption may occur after an initial rise (referred to as *chasm* by Moore) and then increase again producing a saddle in the early growth of the innovation. The Bass model also assumes that diffusion is terminated by the saturation of the market potential. However, in practice, new products are substituted with more advanced products and technological generations.

integrated marketing communication strategy

Ricardo Villarreal

IMC BACKGROUND

In the early 1990s, marketing academics and professionals began to understand the importance of marketing communications consistency in achieving marketing goals and objectives. This understanding was formally organized as integrated marketing communications (IMC) (Schultz, 1991; Moore and Thorson, 1996). Overall, IMC plays an important role in a marketing strategy, especially in terms of branding (*see* BRAND VALUE).

Despite its more than 20-year history, the concept of IMC is still contentious. One fundamental issue with the IMC is how to conceptualize and therefore define it. The conceptual/definitional problem of IMC stems from the fact that it is both a concept and a process (Kliatchko, 2005). A number of conceptualizations and definitions have appeared since the 1980s (Shimp, 2007); for a review of definitions see Kliatchko, 2005. A second fundamental IMC issue is how to measure its impact.

IMC AND THE ENVIRONMENT WITHIN WHICH IT DEVELOPED

IMC emerged as a natural evolution in marketing communications, brought about by drastic changes in the marketplace (*see* MARKET/INDUSTRY STRUCTURE), media and communications, and consumer characteristics (Kliatchko, 2005). Thorson and Moore (1996) and Sirgy and Rahtz (2007) describe specific changes that helped in the formalization of IMC. One identified change is the *decrease in message credibility*. As a result of message clutter, the ability for a single message to have much meaning was rendered almost impossible. A *decrease in the cost of database marketing* (*see* DATABASE MINING AND MARKETING) also helped in ushering the IMC concept. IMC thinking increased in conjunction with the declining cost of gathering, storing, and analyzing consumer data. This allowed firms to identify segment-related characteristics (*see*

MARKET SEGMENTATION AND TARGETING) which lead to identifying important message-related characteristics. A third change in the marketplace was the *increase in the cost of and decrease in the effectiveness of mass media communications*. The number of people watching TV, listening to radio, and reading newspapers began to drop, while the cost to place messages in these media increased. In addition, other media, such as cable, online content, and computer gaming negatively influenced the effectiveness of traditional media. An *increase in mergers and acquisitions of marketing communications agencies* was another change that helped usher in the IMC concept. As a result, agencies were able to put IMC thinking into practice by providing IMC-related services and tasks. Another change was the *increase in media and audience fragmentation*. In the 1980s, the media industry experienced an explosion of content-specific channels and programming, such as sports channels (e.g., ESPN), educational channels (e.g., Discovery Channel), and gender-specific channels (e.g., Oxygen). This fragmentation was associated with an increasing need for multiple messages across a larger number of media and vehicles. The *availability and increase of parity and competing products* (*see* POINT OF DIFFERENCE AND PRODUCT DIFFERENTIATION) also influenced IMC thinking. Clutter at the product level lead to an increased need for product differentiation and the importance of branding (*see* BRAND STRATEGY). Finally, there was a *shift in information technology*. The growth and speed at which the technological environment was changing added to the number of possible new channels (*see* MARKETING CHANNEL STRATEGY) with which to interact with customers.

IMC FEATURES

On the basis of a review of IMC definitions, Shimp (2007) identified five key features. The first feature states that the *consumer or business customer should be the starting point for all marketing communications activities* (*see* CUSTOMER ANALYSIS). A customer focus provides the basis for selecting the most appropriate messages and media. The second feature suggests *using any and all marketing*

2 integrated marketing communication strategy

communications tools that are up to the task. This suggests the importance of learning customers' lifestyles and media preferences in order to know the best context in which to reach them. The third key feature states that *multiple messages must speak with a single voice* in order to consistently and effectively communicate with customers. The fourth feature is *build relationships rather than engage in flings* (see CUSTOMER RELATIONSHIP MANAGEMENT). This implies using the tools that encourage repeat purchasing and enhance brand loyalty (see BRAND VALUE) whenever possible. The final feature states *do not lose focus of the ultimate objective: Affect behavior.* IMC's ultimate goal is to affect consumer behavior above and beyond intermediate goals such as creating brand awareness or attitude change.

IMC TOOLS

The difficulty in implementing IMC lies in selecting and managing possible IMC tools. There are generally eight media categories under which specific vehicle may be selected. Ultimately, brands have to choose those tools that are deemed appropriate for reaching targeted consumers (Shimp, 2007). *Media advertising* is any paid form of nonpersonal communication about an organization, product, service, or idea by an identified sponsor. Advertising tools include television, radio, magazines, and newspapers. *Direct response and interactive tools* (see DIRECT AND INTERACTIVE MARKETING) provide a system by which organizations communicate directly with target customers to generate a response and/or a transaction. Direct response tools include direct mail and telephone solicitation. Interactive marketing allows for a two-way flow of information, and tools primarily consist of online advertising and heavy use of the Internet. *Place advertising* generally refers to advertising seen outside of homes. Place advertising tools include billboards, bulletins, posters, transit, and cinema ads. *Store signage and point-of-purchase advertising* allows consumers to identify and locate businesses and can influence their store-choice decisions and impulse purchasing. Tools include external store signs, in-store shelf signs, shopping cart ads, and in-store radio and television. *Trade-*

and consumer-oriented promotions provide extra value or incentive to the sales force, distributors, or the ultimate consumer. Tools include trade deals and buying allowances, display and advertising allowances, trade shows, cooperative advertising, samples, coupons, premiums, refunds and rebates, contests/sweepstakes, promotional games, bonus packs, and price-off deals. *Event marketing and sponsorship* allows brands to support events and causes that are congruent with the company/brand and consumer's values, interests, or positions. Tools include sporting events, arts, fairs, and festivals, as well as the sponsorship of particular causes. *Marketing-oriented public relations and publicity* are other communication options. Marketing-related public relations is a narrower aspect of general public relations in that it involves an organization's interactions with actual or prospective customers. Publicity is a nonpersonal communication about an organization, product, service, or idea that is not directly paid for nor run under identified sponsorship. *Personal selling* is direct person-to-person communication whereby a seller attempts to assist and/or persuade prospective buyers to purchase a company's product or service or act on an idea.

IMC ORIENTATIONS

IMC can be categorized by either a tactical or a strategic orientation. Some believe the tactical orientation is the simplest and least effective, as it focuses primarily on executional factors such as message cohesiveness and continuity. On the other hand, the strategic orientation may be considered the next step in the evolution of understanding IMC. Its focus transcends the executional by integrating the larger corporate marketing strategy position.

Tactical. According to Parente (1996), *campaign continuity* means all messages communicated in different media through different marketing communications tools are interrelated. It involves making both the *physical* and *psychological* elements of a marketing communications campaign continuous. *Physical continuity* is the consistent use of creative elements in all marketing communications. This can be

achieved by using the same tagline, slogan, and trade characters across all advertisements and other forms of marketing communications. Stern (1996) states *psychological continuity* is a consistent attitude toward the firm and its brand(s). It is the consumers' perception of the company's "voice" and its "persona." Psychological continuity can be achieved by using a consistent theme, image, or tone in different ads and other forms of marketing communications.

Moore and Thorson (1996) identified four general IMC approaches that arguably are tactical in nature. The "*one-look*" approach is based on the strategy of creating a uniform look and feel for all executed messages from colors, fonts, visuals, and logos, in all forms of marketing communication tools. The *theme-lines* or "*matchbook*" approach attempts to coordinate all supporting forms of marketing communications around an advertising theme. The *supply-side planning approach* stems from a marketing communications firm's ability to package for the client a combination of marketing communications media, such as radio, TV, and print for a packaged price. The *ad hoc approach* may be found within integrated agencies or across agencies held by a common parent company.

Strategic Orientation. *Strategic orientation* is a systematic approach that guides firms to fully integrate strategies and objectives at the corporate and marketing organizational levels with all elements of the marketing communications campaign at the planning, execution, and monitoring stages (Sirgy and Rahtz, 2007). That is, every element in the campaign is designed to achieve specific strategic goals and media are selected with strategic goals in mind. The entire marketing and communications system of the firm is integrated toward delivering a unified strategic impact. Strategic marketing communications includes the implicit messages within execution of the four Ps, not just the communications aspect.

IMC BENEFITS

According to Kliatchko (2005), IMC benefits include "the reduction of media waste, improved coordination, centralization, and greater consistency of marketing communications programs,

providing a positive effect on client budgets (see COMMUNICATIONS BUDGETING), and increased message impact and creativity . . ." (p. 12). IMC may reduce media waste by promoting only the selection of target-appropriate media. IMC may have helped lead to the restructuring of marketing communications within companies/agencies, as the conceptualization of IMC may have translated into a physical reorganization within companies/agencies. Presumably, reducing media waste and centralizing people and functions could have a positive budgetary savings effect.

IMC CHALLENGES

Measurement. One of the most important IMC challenges is the inability to truly measure its effectiveness. It has been acknowledged that IMC effectiveness cannot be measured now (Schultz and Kitchen, 2000). IMC is difficult to measure because measurement attempts to focus on output as opposed to outcomes. In addition, "measurement problems are compounded by the fact that IMC programs consist of a variety of communication tools and measuring the interactive effects of all of these elements has proven to be extremely difficult."

Bilingual consumers. IMC is based on two assumptions. The first assumption is that the target consumer speaks only one language. The second is that if a given target consumer speaks more than one language then the consumer will not be exposed to messages for the same company/product in both languages. Research by Villarreal and Peterson (2008) and Villarreal, Blozis and Jeong (2008), however, suggest that these assumptions are not tenable for US Hispanics (see MARKET SEGMENTATION AND TARGETING), as adults and adolescents consume media in both Spanish and English. Villarreal and Peterson suggest that IMC thinking should be reconsidered to account for this phenomenon.

New technology and lack of control. New technology poses an issue for IMC in that this field is constantly and almost consistently changing. It may be problematic for manufactures to keep up with changes in new technology and integrate them (if they are relevant). In addition,

4 integrated marketing communication strategy

new media may become even harder to control in terms of message construction, positioning, and dissemination. For example, YouTube is fertile ground for spoof ads or videos criticizing a particular company. Such grass-root messages have the potential to spread widely and quickly on the Internet.

CONCLUSION

IMC is practiced and conceptualized differently by academics and practitioners alike. However, it is a concept with great appeal and theoretical and practical implications. IMC will most likely continue to evolve in conjunction with our understanding of and changes in our social, technological, and political environments. As Schultz and Kitchen (2000) noted "... IMC is still in a 'pre-paradigm state of development' and that its value will become more evident as further research and experience is obtained through the years."

internal marketing

Ashutosh Prasad

The term *internal marketing* (IM) appears to originate from Berry, Hensel, and Burke (1976). IM is recognized as an important component of a holistic marketing approach. It consists of marketing activities directed toward the employees of the firm as contrasted with the traditional, 'external' marketing.

If we conceptualize *employees as customers*, then IM can be seen as the shaping of their job products to satisfy their needs (Berry, 1981). Although the firm has quite a different relationship with its employees than with its customers, it is possible to find parallels to such external marketing activities as pricing (e.g., transfer pricing, compensation, bonuses), advertising (e.g., internal communications, training media), selling (e.g., face-to-face presentations), segmentation (e.g., team design, functional grouping), acquisition, and retention. This equivalence is appealing because it suggests that there is the potential to apply existing marketing techniques to the IM setting. However, extending the scope of marketing in this manner creates an overlap between the marketing and the personnel functions. To avoid interfunctional conflict, successful implementation of IM programs within the organization requires the support of upper-level management.

The proposal to treat employees as customers emerged from a services marketing (see SERVICES MARKETING STRATEGY) paradigm, with the implied or stated reasoning that satisfied employees would lead to satisfied customers. As George (1990, p. 63) notes, IM "... focuses on achieving effective internal exchanges between the organization and its employee groups as a prerequisite for successful exchanges with external markets."

Employee satisfaction is not an end in and of itself. Thus, a further conceptualization of IM might emphasize that the goal of IM is to increase customer satisfaction (see CUSTOMER SATISFACTION/DISSATISFACTION) by affecting employee satisfaction and other antecedent variables. This follows work, for example, by Grönroos (1985) that IM serves to "... motivate [employees] to customer-consciousness,

market orientation and sales-mindedness by a marketing-like internal approach ..." (see MARKET ORIENTATION). Consistent with this, a textbook states that IM is simply "... training and motivating employees to serve customers well" (Kotler and Keller, 2009, p. 356), adding that, "... marketing functions must be coordinated from the customer's point of view ... [and] other departments must embrace marketing; they must also 'think customer.' Marketing is not so much a department as a company orientation" (Kotler and Keller, 2009, p. 24).

Several researchers have noted that IM can be a vehicle for implementing organizational change (Piercy, 1995; Rafiq and Ahmed, 2000). Rafiq and Ahmed (2000) note that in this role, IM is a planned effort using a marketing-like approach to overcome organizational resistance to change. Thus, a broad scope would be to treat IM as an organizational philosophy through which the firm becomes customer oriented. At the same time, it must be cautioned that while IM, through its employee focus, opens the door to using marketing theories to analyze a range of organizational issues, the fuzziness of its domain likely hampers its widespread adoption.

A large literature exists on IM theory and its use in corporations (Ahmed and Rafiq, 2002; Varey and Lewis, 2000). Prasad and Steffes (2002) discuss a scheme by Continental Airlines that sought to empower and reward employees for exceeding the industry average for on-time flight performance – a simple goal that would increase customer satisfaction and profits. The scheme was promoted by top management, and their active involvement and the obvious expense on IM may have convinced employees, who were initially distrustful of management, to "buy into" the scheme and through their collective involvement make it successful. In the absence of IM, failure could have become a self-fulfilling prophesy. Mitchell (2002) provides an example of what can happen when internal marketing is not used: "The failure of the merger of Deutsche Bank and Dresdner Bank in 2000 can be attributed in part to the failure of management to persuade Deutsche investment bankers of the vision for how the newly formed company would compete. Many key employees left and the threat of a mass walkout forced Deutsche to

abandon the deal after considerable damage to the share price of both companies.”

later mover (nonpioneer) advantage

Peter N. Golder

Later mover (or nonpioneer) advantage results from the challenges faced by first movers and the associated opportunities created for later movers. First movers face five key disadvantages relative to later entrants. In general, the primary challenges in converting a first-mover opportunity into long-term leadership are the high initial degree of market and technological uncertainty plus the dynamic competitiveness of all markets over time (see GO-TO-MARKET STRATEGY).

- *Free-rider effects:* First movers incur high costs to develop new products and the markets for those products. As a result, later entrants can sometimes acquire new technology and other inputs at a lower cost than the first mover. Diffusion of information across firms is one mechanism driving this process (see INNOVATION DIFFUSION). Similarly, later entrants may be able to hire more productive labor because workers already have experience with the new product.
- *Technological discontinuities:* New technologies create opportunities for later entrants to leapfrog first movers and possibly even make first movers' products obsolete. New technologies can lower costs and generate superior product attributes (see RADICAL INNOVATION). Adopting these newer technologies will be easier for later entrants when first movers have already invested heavily in the previous technology.
- *First mover misses consumers' ideal point:* In a new market, it is difficult to determine consumer preferences for the ideal combination of product attributes. If the first mover positions itself in a less desirable location, it may be too slow to reposition to the ideal point or the cost of repositioning may be too high. Meanwhile, a later entrant can learn from the first mover's mistake and position its product at the consumers' ideal point (see CUSTOMER SATISFACTION).
- *Shifting consumer tastes:* Successful first movers are able to identify and satisfy the

needs of at least one market segment (see MARKET SEGMENTATION AND TARGETING). Their products become associated with their successful positioning. Yet, when consumer tastes shift, a first mover's past success becomes detrimental (see CONSUMER INNOVATIVENESS). A later entrant is better able to position its product at the new ideal point of consumers.

- *Incumbent inertia:* First movers may be unwilling to invest in maintaining their initial leadership. In some cases, this reluctance will occur for organizational reasons such as overcommitment to past means of success and unwillingness to cannibalize the current product line (see ORGANIZING FOR INNOVATION; RESEARCH & DEVELOPMENT). In other cases, first movers may have better opportunities in other markets and purposely implement a strategy of harvesting their market share.

Rewards for first movers are much lower than reported in studies initially supporting a first-mover advantage (see FIRST-MOVER (PIONEER) ADVANTAGE for more details). A comprehensive study of both surviving and failed first movers (identified through archival records rather than retrospective recollections) finds a survival rate for first movers of 36%, an average market share of 6% (see MARKET SHARE), and a market leadership rate of 9%. Nearly all first movers and those investing in such ventures expect much higher returns. The same study also finds that many so-called first movers are actually later entrants. Notable examples include Pampers, Gillette, Coca-Cola, and Amazon.com.

In order to overcome these disadvantages, first movers must seek to capitalize on all of the potential first-mover advantages. Often this effort requires firms to experiment with a variety of market and technology strategies until the optimal business model is identified and successfully implemented. Overall, both first movers and later entrants should not expect that entry timing alone will be a major factor in either firm's long-term success. Instead, all firms should focus on persistently developing their new products and new markets, and then relentlessly innovating and pursuing associated

2 later mover (nonpioneer) advantage

market opportunities to capitalize on their past successes.

market definition

Glenn Voss

A product market is an exchange system defined by sellers, offerings, and customers. (*see* MARKET SEGMENTATION AND TARGETING; COMPETITOR ANALYSIS; SUPPLY CHAIN MANAGEMENT STRATEGY) In its simplest form, a product market is a single seller providing a single offering to a single customer. The complexity of the system increases dramatically as the number and diversity of competitors increase, as the number and diversity of offerings increase, and as the number and diversity of customers increase. At its most complex, a product market is synonymous with industry, with multiple competitors offering diverse portfolios of offerings that satisfy the diverse needs of a multi-segment market. This suggests that industry-level analytic frameworks such as Porter's 5 Forces (Porter, M.E. 1980) and product or industry life cycle (*see* STAGES OF THE PRODUCT LIFE CYCLE) can generate product market insights.

Meaningful product market analysis requires careful delineation of the target market (*see* MARKET SEGMENTATION AND TARGETING) and competitive offerings (*see* COMPETITOR ANALYSIS). Target market definition identifies the package of benefits customers are willing to purchase and includes an assessment of relative preferences for variations in benefit dimensions. Relevant competitive offerings include all technologies or solutions used to deliver the package of benefits customers seek. Direct competitors that use similar technologies to deliver comparable offerings constitute a single product market; indirect competitors that use different technologies to deliver substitute offerings may be considered as a distinct product market. This process may yield multiple segments within the product market or segments seeking sufficiently divergent benefits that warrant creation of separate product markets.

It is often useful to define the product market differently for different levels of strategic decision-making. Consider, for example, the worldwide market for cleaning products and one of the largest competitors, Procter & Gamble. At the level of corporate strategy, defining the

product market as all cleaning products for all markets can generate synergies, especially from a supply and production perspective. This macrolevel product market definition also facilitates identifying global demand trends as well as all potential competitors and substitute technologies.

However, to make more effective business and marketing decisions, P&G splits the product market in several ways and organizes and manages its offerings accordingly. First, there is a distinction between business markets and consumer markets. Some of the offerings for the two markets are the same (e.g., Tide and Cheer) and some are unique (e.g., P&G Pro Line Floor Finish Stripper). The purchase and use behavior of the business and consumer markets is sufficiently different to warrant distinct business and consumer divisions responsible for packaging, promotion, sales, pricing (*see* PRICING STRATEGY), channel, (*see* SUPPLY CHAIN MANAGEMENT STRATEGY) and CUSTOMER RELATIONSHIP MANAGEMENT efforts. Within each division, there are additional product market subdivisions. For example, consumer product markets are defined for cleaning dishes and cleaning clothes, among others. The dishwashing product market can be subdivided again into automatic dishwashing needs and offerings, and hand dishwashing needs and offerings. Again, market needs are sufficiently different to warrant distinct consideration of positioning (*see* POSITIONING ANALYSIS AND STRATEGIES), packaging, promotion, and pricing (*see* PRICING STRATEGY) efforts.

Geographic markets and types of channels (*see* SUPPLY CHAIN MANAGEMENT STRATEGY) used to reach end customers also can be useful in defining product markets. For example, soft drink companies like Coca-Cola and Pepsi frequently develop different offerings that satisfy the beverage preferences of different global markets. Coca-Cola and Pepsi create different packaging and delivery offerings for the quick-service restaurant channel (fountain drinks), the supermarket channel (larger packages), and the convenience store and vending channel (single-serving offerings). In each case, customer needs (*see* CUSTOMER ANALYSIS) and competitive offerings (*see* COMPETITOR

2 market definition

ANALYSIS) may be sufficiently varied to warrant distinct product market consideration.

market orientation

Stanley F. Slater, Jakki J. Mohr, and
Sanjit Sengupta

In this article on market orientation we highlight the role of market-based information – about customers, competitors, and other important stakeholders and trends – in strategic decision making. Simply put, information about the market becomes the beacon to guide the company through the messy, oftentimes political, process of strategy making. With a shared understanding of the value and use of market intelligence, a company can create a powerful knowledge-based competency that allows it to gain advantage in the marketplace.

WHAT DOES IT MEAN TO BE MARKET ORIENTED?

Businesses that value close customer relationships and rely on market information to guide strategic decision making are commonly described as market oriented. Market-oriented businesses generate intelligence about customers' current *and* future needs, and about competitors' capabilities and strategies; share that intelligence throughout the organization; and take coordinated action to create superior customer value (e.g., Kohli and Jaworski, 1990; Narver and Slater, 1990).

The effect of market orientation on company performance. A significant body of research has demonstrated a positive relationship between the degree of a firm's market orientation and its performance (see Kirca, Jayachandran, and Bearden, 2005 for an extensive review and synthesis). As shown in Figure 1, by utilizing market intelligence to continuously improve both product quality and service quality, and develop innovative products that meet evolving customer needs, a market orientation delivers superior sales growth and profitability.

Some research has found that the positive relationship between market orientation and firm performance holds true regardless of the environmental conditions in which a firm competes (such as high or low levels of market turbulence, technological turbulence, competitive intensity, and market growth rates)

(Slater and Narver, 1994); however, other studies report that the market orientation/firm performance relationship is *stronger* in highly dynamic markets (Homburg and Pflesser, 2000). Firms must excel not only at generating new innovations that deliver value to customers but also at commercializing these innovations (see LAUNCH STRATEGIES). A strong market orientation without commensurate development of a strong innovation/technological capability (see CORE COMPETENCIES) can have a negative effect on new product and market performance (Baker and Sinkula, 2005).

Activities of the market-oriented business.

Intelligence generation. First, market-oriented firms generate a wide array of intelligence about influential market forces. Market intelligence includes useful information about trends and participants in the market including

- current and future customer needs (see CUSTOMER ANALYSIS);
- competitors' capabilities and strategies (see COMPETITOR ANALYSIS); and
- other important influencers, such as suppliers, as well as important market trends such as socioeconomic and technological change.

Customer intelligence may be generated through traditional market research techniques such as focus groups, customer surveys, customer advisory boards, and feedback from the salesforce (see FOCUS GROUPS AND DEPTH INTERVIEWS). However, the intelligence generated through these processes provides insight only into needs that customers can easily articulate. Responding to customers' expressed needs is usually inadequate to create superior, sustainable customer value since customers for many products may find it very difficult to clearly articulate their needs; they may be unaware of the capabilities that new technologies offer or lack insight into how technology can address their needs. And, even if customers are able to articulate their needs, what they articulate to one seller can and will be articulated to competitive sellers as well.

Firms that primarily act on current intelligence are said to practice a *responsive market*

Figure 1 Market Orientation, Positional Advantage, and Performance.

orientation. Although current intelligence provides important information, some argue that listening to current customers too carefully can inhibit innovation, constraining it to ideas that customers can envision and articulate – which may lead to safe, but bland, offerings. Firms with a responsive market orientation may have a tendency to focus very specifically on solving existing customers' needs with a current technology. Firms that focus too narrowly on their established customers may be constrained in the strategies and technologies they choose to pursue. Such a myopic focus obscures the possibility that customer needs may change over time and may be solved in radically different ways, allowing new, disruptive innovations to creep up like a stealth attack.

For example, a firm's largest and most profitable customers may be the last to embrace a radical innovation and the company may believe that the people who embrace a new technology first, say a simple or inexpensive new technology, may be an unattractive market segment – and as a result, the company pays it little attention. Take the 5.25-inch disk drive, a technology introduced in the early 1980s that was embraced by the emerging desktop personal computer marketplace – yet was inconsistent with mainframe and minicomputer customer demands (Christensen and Bower, 1995). Established disk drive firms did not fail because they were unable to develop innovative technologies. Rather, because established customers were uninterested in new technologies that didn't address their immediate needs, industry leaders did not allocate resources to developing the new technologies. This decision allowed new entrants to gain leadership in the new market.

Businesses that gather anticipatory intelligence have a *proactive market orientation*. Anticipatory customer intelligence is concerned with customers' latent and future needs that

enable the firm to proactively pursue market opportunities that are not evident to competitors. Latent needs are real needs that are not yet in the customers' awareness. If these needs are not satisfied by a provider, there is no customer demand or response. Customers are not necessarily dissatisfied, because the need is unknown to them. However, if a company understands such a need and fulfills it, the customer is "wowed," and rapidly delighted. Offering products and services that address these latent needs in a compelling fashion delights and excites customers and inspires loyalty. A structured customer visit program, ethnographic/observational research, and working with lead users, customers whose needs are more advanced relative to the rest of the market, may provide insight into customers' latent and future needs (see OBSERVATION METHODS; ETHNOGRAPHIC RESEARCH; PERSONAL OBSERVATION; LEAD USERS). While a responsive market orientation may generate incremental innovations, a proactive market orientation is more likely to lead to RADICAL INNOVATION; (Atuahene-Gima, Slater, and Olson, 2005). Therefore, firms must be ambidextrous, combining both responsive and proactive market orientations.

An extreme type of proactive market orientation is known as *market driving* in which a firm actively seeks to (i) redefine the structure of the market (see MARKET/INDUSTRY STRUCTURE) and/or (ii) introduce an innovative value proposition (see A FRAMEWORK FOR CREATING VALUE PROPOSITIONS; VALUE PROPOSITION) that enables the firm to reduce, or even avoid, competition (Jaworski, Kohli, and Sahay, 2000). Market-driving activities may be focused on many different stakeholders including customers and competitors, as well as vendors, potential partners and allies, and regulators. A market-driving strategy can be quite risky since managers are attempting to change

the structure of a market and/or the behavior of players in the market by introducing a discontinuous leap in the customer value system supported by a unique business system. For example, Apple anticipated the emergence of the PDA (personal digital assistant) market when it introduced the Newton in 1993. The Newton Message Pad featured a variety of personal-organization applications, such as an address book, a calendar, notes, along with communications capabilities such as faxing and email. It featured a pen-based interface which used a word-based, trainable handwriting recognition engine. Unfortunately, this engine was notoriously difficult to use which, along with competition from the PalmPilot, led to its cancellation in 1998.

Competitive intelligence can be gleaned through a wide variety of online and off-line resources. The Society of Competitive Intelligence Professionals (<http://www.scip.org>) and the Competitive Intelligence Resource Index (www.bidigital.com/ci/) are two useful starting places. Competitive intelligence can include information on competitors' customer lists, product and pricing information, new-product plans and R&D efforts, job postings that provide insights into new business arenas, information about partnerships, alliances, distributors, and managers, to name a few.

While both customer- and competitor-oriented intelligence generating activities are important, a customer orientation, particularly a proactive orientation, is more strongly associated with a firm's ability to develop new knowledge and skills (*see* MARKET-BASED ASSETS), which, in turn, is more likely to produce breakthrough product and process innovations (*see* INNOVATION TYPOLOGIES). Conversely, competitor-oriented businesses are more likely to invest resources into improving existing products, and hence are more likely to produce incremental innovations.

Regardless of the specific tools used to gather market-based information, it is imperative that the firm allocates resources to the information-gathering process. However, this is much easier said than done. Many firms do not give adequate resources to initiatives that seemingly are not directly tied to underlying product development, commercialization, and

relationship building. Indeed, one \$2 billion US-based high-tech company with which we are familiar was unwilling to invest any meaningful funds to purchase secondary market data, analyst reports, or to undertake its own primary market research. Yet this company wanted to make a "cultural transformation" to being market driven. Clearly, a company that says it wants to become more customer focused must put its money where its mouth is.

Intelligence dissemination. As important as intelligence generation is, the information generated will be of limited value until it is shared across the organization and potentially combined with other information. A firm's knowledge-based competitive advantage – one that increasingly resides in its know-how – is only as strong as its ability to share and use knowledge within and across the organization's boundaries (*see* CROSS-FUNCTIONAL TEAM). Indeed, some say that effective knowledge management requires a boundaryless organization, which takes good ideas from disparate functions and from outside organizations and uses them in many areas. Indeed, as stated by Lew Platt, former CEO of Hewlett-Packard, "*If only we knew what we know*" (cited in Brown and Duguid, 2000). These words reflect a tough truth about most organizations: the knowledge and the know-how of their workforce is too often underused – isolated in departments and functional units.

Market-oriented firms actively encourage sharing of information across people, departments, and divisions. Information may be shared formally in meetings, conferences, newsletters, and databases, or informally through "hall talk" and informal mentoring. People in the organization must be able to ask questions and augment or modify the information to provide new insights to the sender.

However, freely sharing and using information is easier said than done. An organization is a coalition of individuals or groups, each of which has its own goals that may conflict with organizational goals. One way that individuals or departments promote their own self-interests is by creating and protecting their "proprietary" knowledge base. They believe that hoarding or withholding information protects their turf and generates power and status. However, this

dysfunctional belief does not allow the organization to fully leverage its knowledge. Effective dissemination increases the value of information, allowing each piece of information to be seen in its broader context by all organizational players who might be affected by it, use it, or possess complementary information about it.

Thus, the challenge is to create an organizational environment in which group success does not come at the expense of individual success. One way to ensure this is to cultivate a team orientation as the foundation for effective information sharing, a topic that we address later in this article.

Intelligence integration. Third, market-oriented companies must integrate intelligence to create knowledge assets, and they must achieve a shared belief system: a shared interpretation of the information and its implications for the business. Shared interpretation goes far beyond simply sharing the information. Consider this variation on an old joke:

Marketing: The glass is half full.

R&D: The glass is half empty.

Operations: The glass is twice as large as it needs to be.

Each of these perspectives carries substantially different views of what a particular piece of information means, and, by extension, implications for what the firm should do. Integrating intelligence in order to achieve a shared understanding is vital.

Indeed, firms in dynamic and complex markets must strive for consensus internally in order to successfully develop and execute strategy. However, prior to achieving consensus, companies in volatile industries may benefit from a relatively high level of disagreement among managers in interpreting the information they have gathered. Such disagreement allows a closer inspection of the validity of different assumptions and alternatives, as well as an assessment of the relative importance of the company's objectives and competitive methods. In his 1999 book, *Only the Paranoid Survive*, Intel's chairman Andy Grove described his view of spirited debate to his middle managers: "Your criterion for involvement should be that

you are heard and understood All sides cannot prevail in the debate, but all opinions have value in shaping the right answers." A company must reach a shared interpretation of the information it has gathered, but it should not do so prematurely. It should actively facilitate debate, discussion, disagreement, and dialogue in order to fully tap the value of its knowledge.

Coordinated action for implementing decisions. Finally, the market-oriented firm implements decisions through coordinated action. Commitment to execution is necessary for successful implementation of a market orientation. An organization can generate and disseminate intelligence; however, unless it acts on that intelligence, nothing will be accomplished. Mark Hurd, CEO of Hewlett-Packard, quoting Einstein, observed (Murray, 2007), "Vision without execution is hallucination." Acting on market intelligence involves making decisions including the selection of target markets; the development of products/services that address customers' current and anticipated needs; and production, distribution, and promotion of the products to engender both customer satisfaction and customer loyalty (Kohli and Jaworski, 1990).

Moreover, the idea of coordinated action means that all functions in a market-oriented company – not just marketing – participate in responding to market needs. To drive new products from concept to launch more rapidly and with fewer mistakes, "all functional interfaces (contacts) must jointly share in discussions and information exchange" (Gupta, Raj, and Wilemon, 1986). Coordinated action requires a greater emphasis on multifunctional activities – activities that are the joint responsibility of multiple functions in the business. When decisions are made interfunctionally and interdivisionally, a more accurate representation of the information and a closer connection to the market issues will occur. Moreover, interfunctional decision making implies that the people who will be involved in implementing the decisions are the ones actually involved in making the decisions – the idea being that involvement in making the decision makes one more committed to implementing that

decision. Indeed, two firms may have the same information, but what allows one firm to leverage that knowledge more successfully than another is not the knowledge itself, but rather, how that knowledge is coordinated and integrated among different functions and departments.

However, interfunctional rivalry can impede internal knowledge transfer. Functions must compete for scarce organizational resources and are thus often reluctant to share information. This sets up a situation sometimes referred to as *coopetition*, or the simultaneous need for cooperation and competition by various departments within a company. It is true that functional areas compete with one another for resources, but they also cooperate to work toward the firm's common interests. A study of these complicated intraorganizational dynamics found that fostering cooperation but squelching internal competition can actually limit a firm's performance potential (Luo, Slotegraaf, and Pan, 2006). Constructive conflict can promote learning and knowledge sharing, and improve performance. Importantly, market learning is the mechanism by which the simultaneous effects of interdepartmental cooperation and competition are transferred to higher performance. Hence, problems in a firm's market orientation may be due not only to low cross-functional cooperation but also to an inability to assimilate and deploy market knowledge.

In sum, a firm's level of market orientation is determined by its ability to generate and disseminate market intelligence, to come to shared understanding of what that information means, and to make and execute decisions based on the information with cross-functional representation, including multiple departments that are affected by the decisions. How does a company know how market oriented it is? The following section provides guidelines to assess the degree of market orientation of a firm.

Assessing a firm's degree of market orientation. Table 1 contains a set of statements that describe market-oriented business practices. A manager should rate his/her

business on each item using the following scale:

| | | |
|------------------------------|--------------------------------|------------------------------|
| Strongly Disagree (-3) | Disagree Moderately (-2) | Disagree Slightly (-1) |
| Agree Slightly (1) | Agree Moderately (2) | Strongly Agree (3) |

Then sum the scores for the four items in each of the categories. Negative scores indicate much room for improvement, low positive scores indicate the need for selective or incremental improvement, while high scores indicate a strong capability. High scores are relatively rare.

Becoming market oriented: facilitating conditions. The logic for and evidence of the value of a market orientation are clear and compelling. Why, then, are more firms not able to become market oriented? Achieving a market orientation requires a cultural change in the organization. It requires shared values and beliefs about the need to gather, share, and compile market-based information; it requires a common desire to actively discuss the meaning of that information, and to ensure that the company's decisions are soundly grounded in the relevant information. It also requires a resource commitment to the processes involved in a market orientation: data collection expenditures and staffing, time to share and discuss the meaning of the information, and so forth.

The fact is, many firms do not achieve a market orientation because they do not have the proper facilitating conditions in place. These conditions include, at a minimum (i) prioritization of a firm's information gathering focus to match its strategy, (ii) top management advocacy, (iii) a flexible, decentralized structure, (iv), a team orientation, and (v) a market-based reward system.

Prioritizing information gathering needs. Resource constraints coupled with highly complex markets make it impossible to comprehensively scan complex environments. To make sense of complex environments, managers must focus their scanning efforts on the market forces that are most salient to their strategies (*see* MARKETING STRATEGY).

Table 1 Market-oriented business practices.

Responsive Customer Intelligence Generation:

- We continuously work to better understand our customers' needs.
- We pay close attention to after-sales service.
- We measure customer satisfaction systematically and frequently.
- We want customers to think of us as allies.

Responsive Competitor Intelligence Generation:

- Employees throughout the organization share information concerning competitors' activities.
- Top management regularly discusses competitor's strengths and weaknesses.
- We track the performance of key competitors.
- We evaluate the strengths and weaknesses of key competitors.

Proactive Customer Intelligence Generation:

- We continuously try to discover additional needs of our customers of which they are unaware.
- We incorporate solutions to unarticulated customer needs in our new products and services.
- We brainstorm about how customers' needs will evolve.
- We work with lead users, customers who face needs that eventually will be in the market – but face them months or years before the majority of the market.

Proactive Competitor Intelligence Generation:

- We try to anticipate the future moves of our competitors.
- We monitor firms competing in related product/markets.
- We monitor firms using related technologies.
- We monitor firms already targeting our prime market segment but with unrelated products.

Intelligence Dissemination:

- We have interdepartmental meetings to discuss market trends and developments.
- Marketing personnel spend time discussing customers' needs with other functional departments.
- We share information about major market developments.
- Data on customer satisfaction are shared at all levels in the organization.
- When one function acquires important information about customers or competitors, it shares that information with other functions.

Intelligence Integration:

- We have cross-functional meetings for the purpose of intelligence integration.
- We reach organizational consensus regarding the holistic meaning of related pieces of information before taking action.
- We utilize cross-functional teams or task forces for important initiatives to ensure that all points of view are considered before decisions are made.
- Collaboration is valued in this business.

Coordinated Action:

- We are quick to take advantage of market opportunities.
 - The activities of different functions in this business are well coordinated.
 - We make sure that all critical functions understand our objectives and strategy before we take action.
 - There is a high level of cooperation and coordination among functional units in setting the goals and priorities for the organization to ensure effective response to market conditions.
-

Without the ability to simplify, structure, and focus their intelligence generation efforts, managers would suffer from “paralysis by analysis.” One approach to prioritizing their market-scanning efforts is to identify the critical

issues faced by each of four different strategy types. Depending upon whether a company's strategy is a Prospector (product leader), Analyzer (fast follower), Low-Cost Defender (operationally excellent) or a Differentiated

Defender (customer intimate), it will collect and use market-based information differently (Olson, Slater, and Hult, 2005).

Prospectors continuously seek to locate and exploit new product and market opportunities. Owing to the importance of product-market innovation, the most successful Prospectors emphasize proactive customer intelligence generation and generation of intelligence about the development of innovations. Such intelligence can lead either to product performance improvements for current customers or to new products that penetrate new markets.

Defenders attempt to seal off a portion of the total market to create a stable set of products and customers. *Differentiated Defenders* accomplish this by providing superior service and/or product quality. *Low-Cost Defenders* focus on producing goods or services as efficiently as possible so that they can provide their products or services at the best prices. Because the value proposition for the Low-Cost Defender entails producing their products/services as efficiently as possible and offering them at a relatively low price, the most successful Low-Cost Defenders focus their intelligence generation efforts on process rather than on product innovation and on competitors – competitor intelligence provides a benchmark against which prices, costs, and performance can be compared. Differentiated Defenders focus on retaining customers through attention to superior service, product quality, or image. Consequently, the most successful Differentiated Defenders emphasize the generation of customer intelligence and the establishment of strong customer relationships.

Analyzers occupy an intermediate position by cautiously following Prospectors into new product-market domains while simultaneously protecting a stable set of products and customers. In order to identify opportunities for potential product improvements or for entering new market segments, Analyzers must closely monitor customer reactions to Prospectors' offerings as well as competitors' activities, successes, and failures. In other words, while developing customer intelligence is essential for Analyzers, monitoring competitors' actions may be as important to their success.

Top management commitment. If a firm's top managers are not unequivocally and visibly committed to its customers and the collection of market-based information, then the firm will not bring its resources to bear on developing solutions to meet its customers' needs (Jaworski and Kohli, 1993). As Michael Dell, CEO of Dell Computers, once said (Mears, 2003):

"We have a relentless focus on our customers. There are no superfluous activities here. Once we learn directly from our customers what they need, we work closely with partners and vendors to build and ship relevant technologies at a low cost. Our employees feel a sense of ownership when they work directly with customers."

Decentralized organizational structure.

Market-oriented behavior thrives in an organization that is decentralized with fluid job responsibilities and extensive lateral communication processes (Jaworski and Kohli, 1993). Members of these organizations recognize their interdependence and are willing to cooperate and share market intelligence to sustain the effectiveness of the organization. Effective information sharing in a market-oriented organization demands that bureaucratic constraints on behavior and information flow be dismantled. Market uncertainty requires high frequency and informality in communication patterns among organizational units for effective intelligence dissemination.

Team orientation. Team orientation is essential for effective intelligence sharing. In a team-oriented organization, value is placed on working cooperatively toward common goals for which all employees feel mutually accountable. The organization relies on teamwork to get work done. Teamwork has several contributing processes including (i) conflict management, (ii) motivation and confidence building with regard to the team accomplishing its goals and objectives, and (iii) "affect management" which represents those activities that foster emotional balance, togetherness, and effective coping with stressful demands and frustration. Team effectiveness is enhanced when teams monitor progress toward goals, track resources necessary to achieve the team's goals, team members provide direct or indirect feedback to other team

members, and coordinate the activities of team members.

Market-based compensation system. By rewarding employees for generating and sharing market intelligence and for achieving high levels of customer satisfaction and customer loyalty, a market-based reward system is the single organizational factor that has the greatest impact on a market orientation (Jaworski and Kohli, 1993). Market-oriented firms place less emphasis on short-term sales and profit goals than their more financially or internally focused competitors.

At its heart, creating a market-oriented organizational culture within a firm requires a major transformation, characterized by four stages: initiation, reconstitution, institutionalization, and maintenance (Gebhardt, Carpenter, and Sherry, 2006). Essentially, members of the company recognize a threat. To address the threat, a group of empowered managers creates a coalition to mobilize the larger organization; they create a process that reconnects the company's personnel with its customers. Through this process, personnel build common experiences and perspectives and build a consensus for more formal organizational changes to solidify the cultural shift. These formal changes then sustain the new orientation.

SUMMARY

At the most basic level, market-oriented firms excel at generating, sharing, and using information about the market (customers, competitors, collaborators, technology, trends, etc.) to make coordinated decisions that lead to the creation of innovative new products, and superior product and service quality, which lead to superior performance. However, some firms are more proactive than others both in the type of intelligence they generate and in the action they take. The more proactive businesses seek intelligence not only about current customer needs and competitor threats but also about latent and future customer needs and competitive threats. Proactive businesses are more likely to develop market-driving strategies in which a firm actively seeks to redefine the structure of the market, and/or introduce an innovative value proposition that enables

the firm to reduce, or even avoid, competition. A market-driving strategy, while riskier than a responsive strategy, is more likely to lead to a breakthrough position. To successfully transition to being a market-oriented organization, there must be strong leadership from top management, decision making that takes place as close to the customer as possible, and a reward system that recognizes the importance of information sharing and coordinated action.

market evolution

Glenn Voss

A product market is a dynamic exchange system that evolves over time. The number of competitors (*see* COMPETITOR ANALYSIS), the diversity and number of product offerings, and the size and needs of the customer market (*see* CUSTOMER ANALYSIS) are in continuous flux. The industry or product life cycle concept (*see* STAGES OF THE PRODUCT LIFE CYCLE) is one of the best-known frameworks for considering product market evolution. However, the life cycle concept proposes a deterministic progression from introduction to growth to maturity and decline, with the number of firms initially increasing, then decreasing, stabilizing, and ultimately declining. This contrasts with the observation that some product markets seem to remain forever fragmented and with the idea that a product market is a dynamic exchange system.

As dynamic systems, product markets exist along a continuum ranging from relatively stable, incremental evolution to frequent, dynamic, and radical change. Market dynamism is driven by interactions between sellers who experiment with products and prices to increase market share and customers who have heterogeneous and dynamic preferences. These interactions create feedback loops, so that changes in product offerings can lead to altered buyer preferences, which in turn can lead to additional seller innovation and heterogeneity.

Innovation and imitation play key roles in product market evolution. Successful innovation provides advantage to the innovating firm (*see* FIRST-MOVER (PIONEER) ADVANTAGE), with the duration of the advantage largely dependent on the ability of competing firms to imitate the innovation. Where innovation is easy to imitate, imitators tend to outperform innovators because their lower overall cost structure allows for greater margins or lower prices (*see* LATER MOVER (NONPIONEER) ADVANTAGE). However, industry concentration does not occur as long as profitable, imitative firms show restraint in increasing output, which is likely in the absence of economies of scale or scope. Thus, when imitation is easy and economies of scale and scope are modest, both innovation

and imitation can be profitable and product markets can remain fragmented indefinitely (e.g., restaurants and hair stylists).

Product markets tend to consolidate and stabilize when economies of scale or scope are present. If innovation is easy to imitate, imitative firms build scale and scope advantages into dominant positions (e.g., Walmart). Where innovation is difficult to imitate, industries become concentrated as successful innovators (or lucky early imitators) leverage their advantage to build dominant market share (e.g., electronics). As concentration increases, the remaining firms maximize profits by maintaining high margins and limiting capacity increases. The result is a relatively stable oligopoly where dynamism and variety are lower when compared to more fragmented product markets. This is consistent with the maturity stage of the product life cycle (*see* STAGES OF THE PRODUCT LIFE CYCLE).

Oligopolists in stable markets use product offering proliferation to satisfy diverse customer preferences. However, when entry barriers are low and customers seek variety, innovators can enter stable markets with new offerings. For example, the top three brewers dominated the US beer market for decades. And while the top three continue to maintain dominant market share, thousands of craft brewers have entered the market over the last two decades, winning small slices of a large market. Thus, over the last 100 years, the US beer market has evolved from thousands of regional and independent brewers to a small number of dominant oligopolists competing amongst themselves and with thousands of independent craft brewers. This is because some beer drinkers value variety and are innovative enough to support the efforts of small, innovative craft brewers.

market segmentation and targeting

Shikhar Sarin

INTRODUCTION

The concepts of segmentation and targeting lie at the heart of marketing strategy (Best, 2004). In the following discussion, we define and present the rationale for segmentation and targeting, outline the criteria used for evaluating effective segmentation, discuss the commonly used bases for segmenting consumer and business markets, and conclude by describing various approaches for targeting segments.

DEFINITIONS AND RATIONALE

Markets are heterogeneous. They consist of customers with varying needs and preferences. It is very difficult to design a single product or a MARKETING MIX that will satisfy all the customers in a market (Boone and Kurtz, 2001). Marketers therefore divide the total market into smaller, relatively homogeneous groups. This process of dividing heterogeneous markets of dissimilar customers into smaller, more homogeneous subgroups of customers having similar tastes, preferences, and/or needs is called *segmentation* (Boone and Kurtz, 2001; Zikmund and d'Amico, 2001). These resulting subgroups are referred to as *market segments*. Wind and Cardozo (1974) define a market segment as a group of current or potential customers with some common characteristic that is relevant in planning and predicting their response to a firm's marketing stimuli.

Owing to resource constraints, most firms are unable to pursue all the segments they identify in a given market. A firm is likely to focus its marketing efforts on a smaller number of meaningful marketing segments, and concentrate on satisfying these selected segments of the total market (Zikmund and d'Amico, 2001). Zikmund and d'Amico describe targeting as the process of allocating resources effectively by focusing marketing efforts on a selected part of the total market.

Hutt and Speh (2010) note that market segmentation and targeting increase a firm's chances of success by selecting a well-defined

group of potentially profitable customers; focusing marketing resources on these customers; and developing a distinct value proposition (*see* A FRAMEWORK FOR CREATING VALUE PROPOSITIONS; VALUE PROPOSITION) that meets the needs of these customers (in terms of product/service and/or marketing mix) better than the competition (*see* COMPETITIVE ADVANTAGE).

CRITERIA FOR EFFECTIVE SEGMENTATION

Segmentation by itself does not ensure success. In general, four criteria are used to evaluate the effectiveness of segmentation, or the desirability of potential market segments (Hutt and Speh, 2010; Boone and Kurtz, 2001):

1. *Measurability* – the degree to which information on the segment characteristics exists, or can be obtained.
2. *Accessibility* – the degree to which marketers can effectively promote to and serve the market segments.
3. *Substantiality* – the degree to which the segments are large or profitable enough to merit consideration for their own marketing mix.
4. *Responsiveness* – the degree to which the segments respond differently to different elements of the marketing mix (i.e., pricing, product, etc.). Some marketers consider reliability of a segment's response to the marketing mix as an important part of responsiveness as well.

Segmentation attempts to isolate the characteristics that distinguish the buying behavior of a certain group of customers from other groups, or from the overall market (Boone and Kurtz, 2001). These characteristics form the bases for segmentation. Customers can either be individuals (i.e., consumer markets) or organizations (i.e., business markets), and the bases for segmentation used for each market differ significantly. In the following discussion, we cover some of the commonly used bases for segmenting consumer and business markets.

2 market segmentation and targeting

BASES FOR SEGMENTING CONSUMER MARKETS

Bases for segmenting consumer markets are broadly classified under four major categories: geographic, demographic, psychographic, and product-related segmentation (Boone and Kurtz, 2001). Geographic and demographic segmentation are more popular because of their relative ease of use. While information on psychographic and product-related segmentation is harder to come by, these bases of segmentation are considered to be more effective.

Geographic segmentation. Geographic segmentation is one of the most popular approaches to segmenting consumer markets. Marketers often use geography to divide markets when needs and preferences of customers differ based on variables like political or cultural boundaries, climatic regions, and so on. For example, in countries like the United Kingdom and India cars have right-hand drive, whereas they have left-hand drive in countries like the United States. It is not uncommon for global automobile manufacturers like Toyota or Honda to develop a left-hand drive and a right-hand drive model for each car they make to be able to cater to the needs of their consumers in different locations.

People also differ in their preferences across countries and cultures. In Argentina, most Coca Cola is consumed with food, whereas in most Asian countries Coca Cola is consumed independently as a refreshing beverage, and rarely served with meals (Zikmund and D'Amico, 2001). Smart marketers recognize these differences and fine-tune their product offerings and marketing mix accordingly. For example, European countries tend to have smaller living quarters and higher utility rates. Hence, washing machines developed for the European markets often have a smaller capacity but more efficient motors than those sold in the US market, where home sizes tend to be larger and the utility rates lower – resulting in a consumer preference for bigger appliances.

Commonly used sources for geographic information include the census data from various national governments, and Geographical Information Systems (*see* Boone and Kurtz, 2001).

Demographic segmentation. This kind of segmentation involves defining consumer groups based on demographic variables such as age, income, gender, education, occupation, household type, race, and family lifecycle (Boone and Kurtz, 2001). Some illustrative examples are discussed below.

Gender. It has long been assumed that consumer electronics are a male-dominated purchase, with a lot of the advertising for such goods emphasizing technical jargon (Boone and Kurtz, 2001). However, a recent survey by the Consumer Electronics Marketers Association (CEMA) revealed that women are responsible for over half of the consumer electronic purchases. Female consumers look at electronics to serve a practical purpose, to be a tool or a source of entertainment; they find the technical jargon in most consumer electronic advertisements unappealing. On the basis of such information, companies like Microsoft refined their advertising and promotion strategy for women, de-emphasizing the technical jargon and emphasizing the benefits delivered by their products (Boone and Kurtz, 2001).

Age. Online social networking (*see* SOCIAL NETWORKS) sites are very popular nowadays. Many of these sites segment their users based on age. Two of these sites, Facebook and MySpace, target very different kind of users. Facebook users generally tend to be in their 30s, 40s, and older, whereas MySpace tends to target younger users by concentrating their recruitment and promotional efforts on college- and school-age populations.

Family lifecycle. Most adults move through different stages in life such as being single, being married, having kids, raising kids, living together after kids have left the house, and so on. The family lifecycle represents the traditional stages through which most families pass (Zikmund and d'Amico, 2001). Each stage will have specific needs, preferences, and consumption patterns associated with it. For example, first-time parents tend to be heavy consumers of baby items such as cribs, strollers, and diapers. Consumption patterns of parents with kids at home are heavily influenced and driven by the kids (*see* FAMILY BUYING). On

the other hand, single individuals tend to be heavy users of personal care items and consumer electronics (Boone and Kurtz, 2001). Marketers often use stages of family lifecycle to segment their consumers.

Household type. Census data show that across many developed countries, the number of traditional households (i.e., married with kids) is decreasing, whereas the number of nontraditional households such as single parents, people of opposite sex in same living quarters, and double income couple with no kids (DINKS) is on the rise. Each type of household exhibits a specific profile. For example, DINKS have high levels of disposable income, and tend to be big buyers of gourmet foods, luxury items, and travel (Boone and Kurtz, 2001), making them a very attractive segment for such products.

Because data on many of the demographic variables are relatively easy to obtain, demographic segmentation remains one of the most popular methods of segmenting markets. Zikmund and d'Amico (2001) note that some commercially available systems like PRIZM use geographic variables like mail codes to cluster demographically similar individuals to create geodemographic segmentation. While the census information collected varies greatly from country to country, the following sources can offer population statistics for many countries: US Bureau of the Census – International Program Center, United Nations – National Statistics Offices, and Euromonitor – a private market research firm specializing in demographics of European residents (Boone and Kurtz, 2001).

Psychographic segmentation. Psychographic segmentation divides a population into groups that have similar psychological characteristics, values, and lifestyles (Boone and Kurtz, 2001). Lifestyle refers to an individual's life goals – how the person spends his/her time and money (Zikmund and d'Amico, 2001). Consumer's lifestyles are composites of their psychological profiles, needs, motives, perceptions, and attitudes (Boone and Kurtz, 2001).

Quantitative measures of such psychological characteristics, values, and lifestyles are known as *psychographics*. Psychographics provide a ric-

her portrait of the consumer than is possible through simple demographics or geographic variables (Zikmund and d'Amico, 2001). Thus psychographic segmentation is generally regarded to be more effective than either geographic or demographic segmentation, although information on psychographic variables is harder to obtain. Two of the most popular approaches to psychographic segmentation are VALS™ and AIO statements.

VALS™. The name VALS™ stands for values and lifestyles. VALS™ is a commercially available psychographic system developed by SRI Consulting and Business Intelligence, a research and consulting firm. The VALS™ system seeks to divide consumers into different psychographic segments based on two characteristics: (i) primary motivations that lead the consumer to seek a product, service, and/or experience, and (ii) the resources possessed by the consumer which enhance or constrain the expression of his or her primary motivation (Boone and Kurtz, 2001).

Consumer's purchase of products, services, and/or experiences reflects their preferences. It gives shape, substance, and satisfaction to their lives. Primary motivations are indicative of the meaningful core about the self or the world that governs the consumer's activities. The SRI Consulting and Business Intelligence website suggests that consumer's purchases can be inspired by one of three primary motivations: ideals, achievement, and self-expression (<http://www.sric-bi.com/VALS/>). Consumers primarily motivated by ideals are guided by knowledge and principles, whereas those motivated by achievement look for products and services that demonstrate success to their peers. Finally, consumers primarily motivated by self-expression desire social or physical activity, variety, and risk (Boone and Kurtz, 2001).

It should be noted that consumers' tendency to consume goods and services extends beyond simply their age, income, and education. Consumers' energy, self-confidence, intellectualism, novelty seeking, innovativeness, impulsiveness, leadership, and vanity also play a critical role in their tendency to consume. These personality traits together with key demographics of an individual determine the consumer's resources,

4 market segmentation and targeting

which can be either low or high (<http://www.sric-bi.com/VALS/types.shtml>).

On the basis of these three types of primary motivations (i.e., ideals, achievement, and self-expression), and two types of resources (i.e., low and high), VALS™ classifies consumers into eight different segments: innovators, thinkers, achievers, experiencers, believers, strivers, makers, and survivors. Each segment has a specific profile, behavioral and consumption pattern associated with it. For example, thinkers are comfortable, high-resource individuals who are motivated by ideals. They are mature and reflective, and value order, knowledge, and responsibility. Thinkers tend to be well educated, well informed, and seek out information in the decision-making process. Although their income allows them many choices, thinkers tend to be conservative, practical consumers, who look for durability, functionality, and value in the products they buy. The SRI Consulting and Business Intelligence website provides detailed information on the other VALS™ consumer segments (<http://www.sric-bi.com/VALS/>).

SRI Consulting and Business Intelligence have extended this basic approach to create several specialized psychographic systems. For example, GeoVALS™ estimates the percentage of each VALS™ segment in every residential zip code in the United States. Japan-VALS™ segments the Japanese marketplace on the basis of mind-set, emphasizing the identification of early adopters. iVALS™ focuses on Internet sites and users (Boone and Kurtz, 2001). Additional details on the VALS™ survey and other specialized VALS™ systems are available at the SRI Consulting and Business Intelligence website (<http://www.sric-bi.com/VALS/>). The website also lists several examples of the application of the VALS™ system ranging from identification of affluent early adopters by a European luxury automobile manufacturer to repositioning ubiquitous products in commodity categories by a leading US bank. VALS™ remains one of the most popular commercial psychographic segmentation systems.

AIO statements. AIO stands for activities, interests, and opinions. AIO statements are

another popular approach to psychographic segmentation. Here data are collected from respondents related to the degree to which they agree/disagree with statements describing various activities, interests, and opinions (Boone and Kurtz, 2001). These data are used to develop lifestyle profiles of individuals, and group together individuals with similar lifestyle profiles. Marketers then develop separate marketing strategies for each lifestyle segment (Boone and Kurtz, 2001). Boone and Kurtz note that this approach is extensively used for a variety of products and markets ranging from beer to hospitals.

Product-related segmentation. Consumers can also be divided into segments based on their relationship to the product. This approach can take various forms, such as benefits that consumers seek from a product, usage rate for a product, and loyalty toward a product, among others (Boone and Kurtz, 2001).

Segmentation by benefits sought. People may buy the same product for very different reasons. Segmentation by benefits sought approach focuses on segmenting consumers based on the attributes they seek, and the benefit they expect to derive from a good or service. For example, Boone and Kurtz (2001) note that the same box of Arm & Hammer baking soda can end up serving as a baking ingredient, a refrigerator freshener, a toothpaste, or a deodorizer. Thus the baking soda consumers can be divided into various segments based on the reason they are buying the product, or the benefit they are seeking from it. Similarly, motorcycles, as a product, are perceived differently by different consumers. Motorcycles may be primarily perceived as a hobby or a “grown-up toy” in many affluent countries like the United States, whereas in developing countries like India they may be seen as an everyday mode of transportation for the individual or family. The same product would have to be marketed differently to consumers in these countries, or even consumers from different socioeconomic backgrounds within the same country.

Segmentation by usage rate. Consumers use a product or service at different rates. Some consumers tend to be heavy users and others

medium or light users of a product. It is often seen that a relatively small number of consumers account for a large proportion of a product's consumption. This is generally referred to as the *80/20 rule*, that is, 80% of the revenues produced by a product come from a small number (20%) of the customers (Boone and Kurtz, 2001). On the basis of the differences in the needs and preferences of heavy, medium, and light users, firms often market to these groups differently.

Frequent Flier Programs offered by airlines are a good example of this segmentation approach. It is common for airlines to offer priority boarding and baggage handling, free seat upgrades, discount tickets, vacation specials, and other kinds of perks to customers who fly more than a certain number of miles with them (e.g., Medallion members of the Delta Airline frequent flier program). Most airlines use a sliding scale of incentives; the more a consumer flies with them, the more perks are awarded to the consumer.

Segmentation by brand loyalty. Consumers can also be divided into segments based on the loyalty they feel toward a product or a brand. The airline frequent flier program mentioned above can also serve as an example of segmentation by brand loyalty. By offering attractive perks to heavy users and loyal customers, such programs seek to create incentives to develop brand loyalty to their product. Other industries like hotels, car rentals, and even movie rentals practice similar brand-loyalty-based segmentation (Boone and Kurtz, 2001). Research on CUSTOMER RELATIONSHIP MANAGEMENT, customer lifetime value analysis (see CUSTOMER LIFETIME VALUE (CLV)), and database marketing (see DATABASE MINING AND MARKETING) shows that segmenting markets based on brand loyalty and usage rates can significantly increase product margins and even firm profitability.

Some marketing scholars (e.g., Zikmund and d'Amico, 2001) categorize product-related segmentation differently by making a distinction between behavior-pattern-based segmentation (e.g., type of store, shopping frequency, media habits, etc.), consumption-pattern-based segmentation (e.g., usage rate, brand loyalty, etc.), and consumer-predisposition-based segm-

entation (e.g., benefits sought, product knowledge, etc.). A more nuanced treatment of these distinctions is beyond the scope of the present discussion due to space constraints. However, the basic principles discussed above apply in these cases as well. Next, we discuss the bases for segmenting customers in business markets.

BASES FOR SEGMENTING BUSINESS MARKETS

Wind and Cardozo (1974) suggest that the bases for segmenting business markets can broadly be classified into two major categories: macrosegmentation and microsegmentation.

Macrolevel bases. Macrosegmentation centers around dividing the market based on the characteristics of the buying organization (e.g., size, location, industry classification, and organizational structure), and the buying situation (e.g., straight rebuy, modified rebuy, and new task buying).

- *Characteristics of buying organizations* (e.g., size, location, user rate, structure of procurement, etc.). Dividing business markets based on the size of the buying organization is a commonly used segmentation approach. Large organizations often display unique requirements, and respond to marketing mix stimuli differently than smaller organizations (Bellizzi, 1981). Organizations that are heavy users of a firm's product may have needs different than those of light users. For example, businesses that are heavy users may place greater value on technical support or reliable delivery. Similarly, firms having centralized procurement functions may behave differently and emphasize different criteria than firms where the procurement function is decentralized (Hutt and Speh, 2010). Nowadays, the major differences can be seen in firms with primarily online procurement processes versus those with primarily offline procurement processes. Sometimes location of the buying firm can affect issues like the cost, delivery, and level of regulation involved. All of the above factors can influence the buying behavior of business customers, and be

6 market segmentation and targeting

used as a basis for differentiating marketing strategies.

- *Product/Service application* (e.g., industrial classification, end market served, value in use, etc.). Industrial goods can be used in many different ways (e.g., industrial gases). Often the applications and the needs of the customers can vary based on the industry of the buying organization. Hence business marketers can segment industrial markets based on industry classification, end-use application, end market served, or the product's economic value to the user relative to a specific alternative in a specific application (Hutt and Speh 2010). For example, Hutt and Speh note that Intel's microprocessors can be used in many different applications and industries ranging from household appliances, cell phones, computers, to toys. The marketing strategies employed by Intel for each of these industries would differ considerably based on end-use application and industry-specific requirements and needs.
- *Characteristics of purchasing situation* (e.g., type of buying situation, stage of purchase decision process, etc.). Information and customer service needs of a first-time buyer (i.e., new task buy) are likely to be very different from those of a repeat buyer (i.e., straight rebuy or modified rebuy). Thus the position of the buying firm in the purchase decision process (i.e., early or late) or the buying situation can dictate the marketing strategies employed. For example, vendor comparison/evaluation may play a much more prominent role in a new task buy or modified rebuy situations compared to a straight rebuy situation. Thus marketers can gain sales by designing appropriate strategies for customers in the new task or modified rebuy situations. Conversely, failure to account for differences in customers based on purchase situations can leave marketers vulnerable to competitive action.

Microlevel bases. Microsegmentation focuses on the decision-making units within each macrosegment and requires greater marketing knowledge (e.g., key buying decision criteria,

attitude toward the vendors, and perceived importance of the purchase) (Wind and Cardozo, 1974).

- *Key criteria* (e.g., vendor reliability, price, technical support, delivery, etc.). For some business products, markets can be divided on the basis of key criteria that customers consider most important for the purchase decision (Hutt and Speh, 2010). For example, based on the value proposition sought by customers (*see A FRAMEWORK FOR CREATING VALUE PROPOSITIONS; VALUE PROPOSITION*), the chemical giant Dow Corning segments its markets into innovation-focused customers, customers in fast-growing markets, and customers in highly competitive markets (Hutt and Speh, 2010). Similarly, Rangan, Moriarty, and Swartz (1992) note that in mature industrial markets, customers could be segmented into four categories based on price-service trade-offs: programmed buyers (i.e., buyers insensitive to price or service), relationship buyers (i.e., buyers that value partnerships and do not push for price or service concessions), transaction buyers (i.e., buyer that actively consider price vs. service trade-offs), and bargain hunters (i.e., buyers who are very sensitive to any price or service change).
- *Purchasing strategies* (e.g., single sourcing vs. multiple sourcing). Some business markets can be segmented on the basis of the buyer's purchasing strategies. Some buyers purchase from a single supplier, or a very small number of suppliers, giving each a healthy share of their business in exchange for a stronger relationship and preferred treatment (Hutt and Speh, 2010). Other buyers tend to employ a larger number of suppliers in an effort to reduce their risk, prevent any disruption in their supplies, or even maintain a stronger position relative to their suppliers.
- *Structure of the decision-making unit* (e.g., purchase manager vs. buying center, etc.). Structure of the decision-making unit at the customer end (or buying center) can also provide a basis for segmenting business markets. Depending upon which participants are involved in (or exert

influence over) the purchasing process (e.g., purchasing manager, engineering, senior management, etc.), marketers can fine-tune their presentation or marketing mix in each segment to take into account the dynamics of the decision-making units. Sometimes this approach also takes into account the personal characteristics (i.e., age, education, decision-style, and risk propensity) of the key decision makers at the customer end.

- *Organizational innovativeness* (e.g., innovator, follower, etc.). Robertson and Wind (1980) note that firm psychographics and demographics can be used to predict the adoption of new products by organizations. For example, some organizations are resistant to change, while others are more innovative and have a desire to excel. Robertson and Wind suggest that the latter are more likely to purchase new industrial products than the former. Marketers can use such organizational innovativeness variables to identify segments of business markets to target first when introducing new products (Hutt and Speh, 2010).

TARGETING

Owing to resource constraints, firms are often unable to pursue all the segments they identify in a given market. Typically, firms focus their marketing resources on satisfying a smaller number of segments in the market (Zikmund and d'Amico, 2001). This process of allocating resources effectively by focusing marketing efforts on a selected part of the total market is called *targeting* (Zikmund and d'Amico, 2001). By focusing their limited resources on the targeted segments, firms are able to compete effectively in those segments by developing a distinct value proposition better than their competitors (Hutt and Speh 2010). The targeting strategies that firms follow can broadly be classified into four major categories: undifferentiated marketing, differentiated marketing, concentrated marketing, and micromarketing (Best 2004; Boone and Kurtz 2001; Porter 1985; also see COMPETITIVE ADVANTAGE).

Undifferentiated marketing. In undifferentiated marketing, a firm produces only one product or

product line, and promotes it to all the customers with a single marketing mix (Boone and Kurtz, 2001; Porter, 1985). Such an approach is also referred to as *mass marketing*. An undifferentiated marketing approach is seen when differences in customer needs and/or demographics are either small or indistinct (Best 2004). This targeting strategy presents a generic business strategy with generic positioning, built around a core product (Best, 2004).

While such a strategy might be efficient from a production standpoint, it leaves firms vulnerable to competitive action (Boone and Kurtz, 2001). Firms following an undifferentiated targeting approach can suffer if competitors are able to successfully differentiate the market. That is, competitors enter the market with specialized products and marketing mix that are able to better meet the needs and preferences of smaller segments of consumers within the overall market (see COMPETITIVE ADVANTAGE). Although less frequently used now, a prime example of undifferentiated strategy is the marketing of the Ford Model T. Henry Ford built the Model T and sold it at one price to everyone. He was famously known to have said that he was willing to give the customers any color car they wanted – as long as it was black (Boone and Kurtz, 2001).

Differentiated marketing. Under this strategy, firms promote numerous products with differing marketing mixes designed to satisfy customers in smaller segments (Boone and Kurtz, 2001). In each segment, the firm selects one or more dimensions that the customers value and uniquely positions itself to meet those needs – while charging a premium price for such uniqueness (see POINT OF DIFFERENCE AND PRODUCT DIFFERENTIATION; COMPETITIVE ADVANTAGE; PRODUCT POSITIONING). Porter (1985) suggests that several sources can provide the bases for differentiation, such as the product itself, the method of delivery/distribution, the marketing approach, and so on. Compared to an undifferentiated approach, a differentiated strategy allows a firm to increase not only its total sales (Boone and Kurtz, 2001), but also its average margin per sale (Best, 2004), by providing increased satisfaction to each of the targeted segments.

8 market segmentation and targeting

A differentiated strategy increases marketing costs. However, despite increasing costs, firms are forced to practice differentiation in order to remain competitive (Boone and Kurtz, 2001). Porter (1985) suggests that in order to remain competitive and counter increasing costs associated with a differentiation strategy, firms must strive for cost parity with their competitors by reducing costs in areas that do not affect differentiation.

Many products and services follow a differentiation strategy. For example, most major airlines offer economy class, business class, and first class seating based on how much value passengers place on their comfort and service while traveling. Similarly most automobile companies offer a variety of cars ranging from sedans, to convertibles, to minivans, and so on, based on the needs and preferences of the various segments in the market.

Concentrated marketing. Rather than trying to market its product or service to multiple segments, a firm may choose to use its marketing resources to profitably satisfy customers in a single market. Such a targeting strategy is known as *concentrated*, *focus*, or *niche marketing* (Boone and Kurtz, 2001; see COMPETITIVE ADVANTAGE). By deliberately electing to narrow the scope of its activities, a firm seeks to achieve competitive advantage in the niche segment targeted, even though it may not enjoy a competitive advantage overall (Porter, 1985). A concentrated marketing strategy works well when the targeted niche segment has needs or preferences that are poorly served by more broadly targeted competitors. Under such conditions, a firm can exploit these differences and achieve competitive advantage by dedicating itself to serving the niche segment(s) exclusively (Porter, 1985).

A focus/niche targeting strategy generally appeals to small firms that lack the financial resources of its competitors, or to companies that offer highly specialized goods and services (Boone and Kurtz, 2001). Sub-Zero Refrigerators are a good example of successful niche segmentation. Sub-Zero specializes in very expensive, built-in refrigerators that start at \$3500 per unit. While Sub-Zero has less than a 2% share of the overall refrigerator market

in the United States; it commands a 70% market share of the “Super Premium” (i.e., high end) segment – a niche segment within the refrigerator market (Best, 2004).

Micromarketing. Micromarketing, also known as *mass customization*, refers to a focus even narrower than concentrated or niche marketing. It represents the polar opposite of an undifferentiated strategy. Micromarketing involves targeting potential customers at a very basic level, that is, postal code, occupation, household, and so on, and ultimately the individuals themselves (Boone and Kurtz, 2001; see MASS CUSTOMIZATION STRATEGIES). Under this targeting approach, the smallest group of unique customers is treated as a niche segment, and the firm develops a customized segment strategy for it, even if the segment consists of a single individual (Best 2004).

Increasing use of database marketing (see DATABASE MINING AND MARKETING) and internet marketing (see E-COMMERCE AND INTERNET MARKETING) allows the tracking of specific demographic, personal, and web browsing information, making it easier for marketers to engage in effective micromarketing (Boone and Kurtz, 2001). For example, Amazon.com, the giant online book and music retailer, provides its customers with individualized recommendations based on his/her web browsing patterns and past purchase behavior.

CONCLUSION

The concepts of segmentation and targeting lie at the heart of marketing. Segmentation is the process of dividing heterogeneous markets into homogeneous subgroups, which display similarities in needs, preferences, and/or behaviors. Segmentation allows firms to develop a marketing mix better suited to the customers in each segment. Four criteria are used to determine effective segmentation: measurability, accessibility, substantiality, and responsiveness of the segment(s) selected. However, due to resource constraints, firms are often unable to pursue all the segments they identify in a market. They have to select or target the segments they would like to pursue.

The preceding discussion briefly outlines the bases commonly used to segment consumer and

business markets. In consumer segmentation, we discussed geographic, demographic, psychographic, and product-related approaches to segmenting markets. In business segmentation, we covered macrolevel bases of segmentation (i.e., characteristics of the buying organization, product/service application, and characteristics of the purchase situation) as well as microlevel bases of segmenting business markets (i.e., key criteria, purchasing strategies, structure of decision-making units, and organizational innovativeness). We conclude by describing four popular targeting strategies: undifferentiated marketing, differentiated marketing, macromarketing, and micromarketing.

Owing to space constraints, the discussion here cannot exhaustively cover all the issues pertinent to market segmentation and targeting. Readers may wish to refer to the articles on positioning (*see* POSITIONING ANALYSIS AND STRATEGIES), pricing (*see* PRICING STRATEGY), and forecasting (*see* NEW-PRODUCT FORECASTING), for additional details on related topics.

market share

Derek N. Hassay

Perhaps the most commonly referenced marketing metric (*see* MARKETING METRICS) Market share is defined as *the proportion of a market segment (see MARKET SEGMENTATION AND TARGETING) served by a company*. Market share can be reported as a percentage of revenue or unit sales volume according to the following formula:

$$\begin{aligned} \text{Market share(\%)} \\ = \frac{\text{Company (unit or \$) sales}}{\text{Total industry (unit or \$) sales}} \times 100\% \end{aligned} \quad (1)$$

An especially powerful metric, market share reflects both a company's performance relative to its *competitors* (*see* COMPETITIVE ANALYSIS) and the success of its MARKETING STRATEGY. Though simple to calculate, in practice, determining *competitive sales* (*see* COMPETITOR ANALYSIS) or consumer purchases for a given PRODUCT CATEGORY in a specific market can be a significant challenge. For instance, capturing sales information for a geographic market segment is far simpler than for a demographic (e.g., young males, low income) or psychographic (e.g., recreational athletes) segment. Moreover, the actual definition of a market is subjective and thus by narrowly defining its served market, a firm can report a larger market share and thus enhance its *market position* (*see* POSITIONING ANALYSIS AND STRATEGIES). For instance, a manufacturer of automobiles might suggest that it is the sales leader in the Northwest, where the Northwest has been narrowly defined as Washington State.

Market share is commonly cited as a key determinant of profitability, as firms with larger shares are generally thought to be more profitable than those with smaller shares in the same market because of economies of scale, reduced cost of marketing relative to sales, and higher prices (Buzzell, Gale and Sultan, 1975). The Profit Impact of Marketing Strategy (PIMS: Buzzell and Gale, 1987) studies, conducted by the Strategic Planning Institute, identify market

share and relative market share (the proportion of a firm's share relative to its largest competitor) as two of 18 key strategic variables influencing business success or profitability. The often cited PIMS studies, highly regarded because of the volume of data they have captured on strategic business variables since the early 1960s (Strategic Planning Institute), indicated that market position factors such as market share have the most significant impact on profitability.

Despite the volume of articles, textbooks, and frameworks reporting market share as a key determinant of profitability, having greater market share is not necessarily synonymous with increased profitability. Schwalbach (1991), for example, demonstrated that the proposed linear relationship between share and profitability is flawed and argued that the true relationship between share and profitability is much more complex. In fact, it was suggested that while *correlated* (*see* PRODUCT MOMENT CORRELATION), the *causal relationship* (*see* CONCEPT OF CAUSALITY AND CONDITIONS FOR CAUSALITY) between share and profitability may actually be reversed with higher profits enabling greater market share growth (Davidson, 1985). Subsequent research efforts revealed that the theoretical underpinnings of the share–profitability relationship – the experience curve – did not have the pronounced impact on profitability as originally thought nor did it hold across different types of industries (Davidson, 1985). This information prompted the Boston Consulting Group to produce a new BCG Matrix (Hax and Majluf, 1983), as its original portfolio planning tool based on relative market share and economies of scale was inaccurate. The new BCG matrix examined the relationship between ROI and market share in four unique industry contexts (Hax and Majluf, 1983).

At the very least, profitability is likely to suffer in the short term when a firm pursues market share growth because competitor-oriented objectives such as this typically require increased marketing expenditures. And in those cases where a firm is close to capacity or has to expand *distribution* (*see* MARKETING CHANNEL STRATEGY) beyond regional or national markets, any increase in market share will require a concomitant investment in production, inventory, and distribution capabilities.

2 market share

Recent research calls for firms to become more customer than competitor-centric and to manage *customer relationships* (see CUSTOMER RELATIONSHIP MANAGEMENT) for long-term profitability. Reinartz and Kumar (2002) found that some customers actually have a negative impact on profitability, while Zeithaml, Rust and Lemon (2001) cautioned firms against using profitable customers to subsidize the service of unprofitable ones. Sharma (2008) argued that rather than spending valuable marketing efforts on unprofitable customers, firms may need to outsource or even fire some customers, a position which suggests that, in these instances, a lower market share is likely to lead to increased profitability.

market/industry structure

Joseph A. Cote

Economics categorizes markets as perfect competition, monopolistic competition, oligopoly, or monopoly – with a focus on policy implications. Marketing differs, emphasizing the managerial implications of market structure. Marketing defines market/industry structure as the characteristics of a competitive space (*see* COMPETITIVE ANALYSIS) that affect MARKETING STRATEGY and tactics. The effects of market/industry structure can be examined using a wide variety of frameworks including Porter's model, the marketing environment, critical success factors (*see* SUCCESS FACTORS FOR NEW-PRODUCT DEVELOPMENT), the resource-based view, stakeholder relationships, network effects, value chain analysis, product life cycle (*see* STAGES OF THE PRODUCT LIFE CYCLE; PRODUCT LIFE CYCLE), and prototypical business models (*see* MARKETING STRATEGY MODELS). The more prominent frameworks are summarized below.

FIRST STEP

The market/industry must be defined before conducting a market/industry structure analysis (*see* MARKET ORIENTATION). NAICS or SIC classification codes can be used, but a rigorous analysis should consider the levels of competition. Competition can occur within a PRODUCT CATEGORY (e.g., beer), across closely related product categories (e.g., wine and liquor), or across any relevant product category (e.g., beverages). Knowing the alternatives considered by consumers (*see* CUSTOMER ANALYSIS) allows you to more accurately define the competitive space. For example, cruise companies not only compete among themselves but also with a host of other vacation and “staycation” options.

PORTER'S MODEL

Porter's model is often used to evaluate the overall attractiveness of an industry (Porter, 2008; Porter, 1979). He examines industry attractiveness using five forces: existing competition (*see* COMPETITOR ANALYSIS), buyers

(*see* MARKETING CHANNEL STRATEGY), suppliers (*see* SUPPLY CHAIN MANAGEMENT STRATEGY), substitutes, and potential competitors. Porter argues that, “Industry structure, as manifested in the strength of the five competitive forces, determines the industry's long-run profit potential because it determines how the economic value created by the industry is divided . . . ” (Porter, 2008, p 86). For example, high economies of scale can prevent new competitors from entering a market, lowering competitive intensity. Conversely, DEMAND ELASTICITY among buyers will increase competitive intensity. Understanding the five forces also provides insights into prices, costs, necessary investments, and potential shifts in the industry.

THE MARKETING ENVIRONMENT

A marketing environment analysis is used to understand the underlying drivers that determine success or limit a firm's actions (*see* Figure 1). In addition to suppliers, buyers, and competitors, the marketing environment considers macrolevel conditions and trends related to economic, political/legal, technological, and social/cultural/demographic (*see* SOCIETY, CULTURE, AND GLOBAL CONSUMER CULTURE) issues. For example, during the 2008–2009 economic crisis, auto makers had to significantly change how they did business since consumers were either unable or unwilling to obtain loans to purchase new vehicles. Similarly, demographics trends (aging population and increasing incidence of obesity) have significant implications for the health-care industry and proposed regulations of greenhouse gases may significantly affect power generation and energy companies.

CRITICAL SUCCESS FACTORS AND KEY RESOURCES

Leidecker and Bruno define critical success factors (CSFs) as “those characteristics, conditions, or variables that when properly sustained, maintained, or managed can have a significant impact on the success of a firm competing in a particular industry.” (Leidecker and Bruno, 1984, p 24). For example, customer retention (*see* CUSTOMER LIFETIME

Figure 1 The marketing environment.

VALUE (CLV); CUSTOMER RELATIONSHIP MANAGEMENT) is often a CSF for monthly subscription services such as cell phones and health clubs. Once the critical success factors have been identified, firms can then develop strategies and key resources (*see* CORE COMPETENCIES) to address these factors, thus creating COMPETITIVE ADVANTAGE (*see* COMPETITIVE ADVANTAGE: ITS SOURCES AND THE SEARCH FOR VALUE) (per the resource-based view, *see* Barney, 1991).

STAKEHOLDER ANALYSIS

Freeman 1984 suggests that an organization's success depends on its relationships with employees, customers, value chain partners, financiers (investors, banks, etc), and the public (communities, government, etc). Understanding how each stakeholder affects the organization helps management design strategy to best leverage these relationships. Stakeholders often provide the key resources necessary for competitive advantage. For example, Apple's ability to work with content providers on digital rights management allowed them to create iTunes and a dominant position in music distribution. Stakeholder analysis is often used to look beyond the obvious players to understand how others affect an industry (Fassin, 2009).

NETWORK EFFECTS

Increasingly, industries are defined by networks rather than individual companies or products. Network relationships provide access to information, markets, technologies, etc., and

the pattern of network relationships can affect performance (Gulati, Nohria, and Zaheer, 2000). For example, the iPhone relies on a network of independent developers to create applications. The types and number of applications help create competitive advantage for the iPhone. Networks can also be product based (Lee and O'Connor 2003). For example, digital cameras became more useful when flash memory, desktop printers, image processing software, and CCD technology improved.

marketing audit

Bruce H. Clark

The term *marketing audit* is generally thought to have been introduced into the marketing literature in an American Management Association report (American Management Association, 1959). For a thorough history of the concept and its development, see Rothe, Harvey, and Jackson (1997). The use of the term *audit* is an explicit analogy to the accounting audits performed for companies on a regular basis.

DEFINITION AND PURPOSES

The most widely used definition of the construct is provided by Kotler, Gregor, and Rodgers (1977) in an influential *Sloan Management Review* article. They define a marketing audit as follows:

A marketing audit is a comprehensive, systematic, independent, and periodic examination of a company's—or business unit's—marketing environment, objectives, strategies, and activities with a view to determining problem areas and opportunities and recommending a plan of action to improve the company's marketing performance (p. 27).

Kotler, Gregor, and Rodgers (1977) further distinguish between a *horizontal audit* covering the full scope of a company's marketing activities, and a *vertical audit* that examines a particular marketing function in depth (e.g., a sales force audit or an advertising audit).

As the definition suggests, audits are both backward-looking and forward-looking. They seek to evaluate past and current marketing assets (see MARKET-BASED ASSETS) and activities in the context of market conditions, but use the resulting analysis to aid the firm in planning. Some writers refer to auditing explicitly as a control function in this regard (Brownlie, 1996). Mokwa (1986) also notes that audits can perform an important educational function for the firm in terms of improving awareness and comprehension of marketing issues.

ELEMENTS OF AUDITS

Unlike an accounting audit, there are no formal standards for conducting marketing audits. Both Mokwa (1986) and Brownlie (1996) argue that this is a truth rather than a limitation: audits invariably must be customized to the firm being audited. That said, most discussions suggest an audit should cover both an analysis of the external situation facing the unit and a thorough review of internal marketing goals, strategies, capabilities, processes, and systems. In this sense, a formal situation analysis or SWOT ANALYSIS is an important part of the audit. Audits differ from SWOT analysis, where the “comprehensive, systematic, independent, and periodic review” indicated in the definition generates a deeper, more objective (and iterative) learning, and planning process. The literature contains several comprehensive frameworks that cover likely areas of interest to auditors (see Kotler, Gregor, and Rodgers, 1977; Mokwa, 1986; Berry, Conant, and Parasuraman, 1991; Brownlie, 1996; Wilson, 2002).

THE AUDIT PROCESS

Auditors use an audit framework to conduct a structured consulting project that identifies ways in which the audited firm can improve its marketing. The audit may be conducted by either internal or external auditors, but auditors must be independent of the audited unit in either case. Most authors argue that conducting regular, periodic audits maximizes the value of the process. For a given firm, having a common framework applied over time will aid in developing more long-term learning. Regular audits also avoid the fear employees sometimes have that an ad hoc audit is a prelude to unwelcome changes. Brownlie (1996) covers audit process issues particularly well. Enis and Garfein (1992) also outline a computerized approach to auditing.

EMPIRICAL EVIDENCE

It is difficult to tell how widespread marketing audits are, partly because many firms may engage in elements of an audit (e.g., situation analysis) without calling the process an “audit.” Trade coverage of audits suggests service applications are particularly common (see Berry, Conant, and

2 marketing audit

Parasuraman, 1991 for good coverage of the elements of a service audit). Despite a compelling logic to the process, there is also little evidence beyond case studies regarding the benefits of conducting audits. One exception is Taghian and Shaw (2008), who find a positive correlation between conducting marketing audits and (self-reported) change in market share and financial performance.

RELATIONSHIP TO OTHER CONSTRUCTS

The marketing audit is typically seen as one way of evaluating the health of a firm's marketing practices. In this sense, it is strongly related to broader research on marketing performance measurement (Bonoma and Clark, 1988), marketing control (Jaworski, 1988), MARKET ORIENTATION, and the more recent movement toward marketing accountability and MARKETING METRICS.

marketing costs

Mukesh Bhargava

Almost a century ago, Shaw (1912) explored the problems in distribution focusing on reducing marketing costs and improving the productivity. The themes of cutting marketing costs and increasing efficiency explored in that paper still resonate today. Marketing costs account for the largest part of the consumer dollar. The prefix “cutting” features in most current articles on marketing costs. Further, a large number of articles link lack of profitability to escalating marketing costs. We need to build the perception that marketing costs produce value, and should therefore be viewed as investments in building the assets of a firm (*see* MARKET-BASED ASSETS).

MARKETING COSTS AND TACTICS

Most marketing textbooks discuss cost under a section on Marketing Arithmetic covering topics such as margins, fixed and variable costs, and breakeven analysis. Marketing costs are mentioned, usually qualitatively, while detailing the marketing mix decisions. Some of the examples are costs associated with the following:

1. Product quality, packaging, logo and brand development, and brand extensions.
2. Price decisions covering fixed and variable costs, breakeven analysis, and the demand (*see* DEMAND ELASTICITY).
3. Distribution requiring an analysis of transportation, inventory carrying, distribution margins, incentives to “push” products including allowances to trade.
4. Communication budgets including allocation by promotion mix and media selection, and agency compensation (*see* COMMUNICATIONS BUDGETING).

Most material does not provide any detail about the amounts as the figures vary by product, product lifecycle, and country. However, in some industries such as pharmaceuticals and healthcare, and government and nonprofit organizations, marketing costs are often portrayed as being wasteful (Gagnon and Lexchin, 2008).

MARKETING COSTS AND STRATEGY

Strategically, lower costs provide competitive advantage. The costs can be lower because of economies of scale, where the volume provides a lower unit cost per item. The other methods of decreasing costs include lowering costs of production through a learning curve. Additionally, economies of scope also can lead to lower costs. These include cost advantage in brand extensions, distribution coverage as well as the use of marketing knowledge and processes for new-product development and commercialization. Cost analysis provides an indication of the “strategic group” that the firm will be competing against. All of these factors can lead to greater efficiencies, assuming that the company is doing “things” right. Unfortunately, while cost-based metrics help us to improve the marketing efficiency, it is the issues of being effective that really need to be addressed.

MARKETING COSTS AS INVESTMENTS

In the last decade, there has been a renewed interest in computing the return on marketing investments, that is, trace the costs and the benefits. The presence of better databases allowed the estimation of cost of new-customer acquisition and the lifetime value of a customer. However, generally acceptable practices for relating costs and results, the foundation to the application of tools from accounting and finance, have yet to emerge (Farris *et al.*, 2006). (*see* MARKETING METRICS).

There are numerous complicating factors that introduce complexity in developing the “true” returns of marketing investments. Marketing costs are expensed over a time period, whereas there is adequate research that shows that the outcomes (e.g., new customers, creating a brand name, better relationship with channel members) lead to an increased cash flow in the future. Other complicating factors are as follows:

1. Marketing activities are dispersed both within and outside the functional unit.
2. Manufacturing costs are allocated over products, whereas the marketing costs allocation has multiple, conflicting basis such as products, territories, channels, size of orders, and even sales force.

2 marketing costs

3. The outcomes are influenced by competitive actions and other exogenous variables over which the company and the manager do not have direct control.
4. There are numerous alternatives for product development, pricing, communication, and distribution, which merge online and offline tactics.

The analysis of the cost of marketing can be done at the national, industry, firm, brand, channel, advertising campaign, package sizes, and customer levels (Doyle, 1998). Aggregation of data by time period and level of analysis often masks vital information necessary for any meaningful analysis. The crucial problem is that relevant cost data that companies are willing to share is extremely limited. As a result, there is a paucity of academic work on net results of marketing activities (net margins, cash flow, etc.).

The silver lining in the appropriate use of costs and returns as managerial tools in

marketing is the development of fine-grained data for each customer and product (stock keeping unit (SKU)) and time periods. Given these developments, it is possible to conduct experiments that provide a better measure of marketing costs and returns.

marketing channel strategy

Anne T. Coughlan

INTRODUCTION

Marketing channel strategy – one of the “Four P’s” of the marketing mix (“place,” along with product, price, and promotion (*see* MARKETING MIX)) – comprises the set of decisions made, and structures created, that help move a manufacturer’s product or service from its place of manufacture to the ultimate end-user. Unlike the other three “P’s,” it inherently involves collaboration and interaction among multiple corporate entities, all in the pursuit of a single goal: profitable end-user sales. The strength of partnering with other companies or entities is the access it affords to partners’ capabilities. The corresponding challenge is the structuring and ongoing management of a complex set of activities, undertaken across corporate borders, without complete control. This article lays out the key elements of effective channel design and channel management.

MARKETING CHANNEL DEFINITION AND ELEMENTS

A “marketing channel” (also called a “distribution channel” or “route to market”) is defined as follows:

A marketing channel is a set of *interdependent* organizations involved in the *process* of making a product or service *available for use or consumption*.¹

This definition highlights three concepts important in managing a marketing channel. Consider the italicized terms in the definition, in reverse order.

First, a channel’s very purpose is to make its product or service *available for use or consumption*. This means that the primary focus is always on end-users and their satisfaction. As a marketing concept, this hardly seems earth-shattering; after all, do we not start every analysis with the consumer or end-user? Sadly, this is often *not* the case when managers consider their channel strategies. For example, a manufacturer selling to the ultimate end-user through a retailer may erroneously consider the retailer a “customer.”

In fact, the retailer is not the manufacturer’s customer, but a *partner* in *jointly* serving the ultimate end-user (who is the true consumer).

An easy way to verify the identity of the end-user is to ask the question, “Who pays the channel’s bills?” Only ultimate end-users inject fresh money into the channel and thus pay for all the costs of running the channel, as well as any profits above and beyond those enjoyed by all channel members.

Secondly, running a marketing channel is a *process*, rather than an “event” happening at the moment of sale. Distribution involves the cumulative investment of time and effort, usually by multiple channel members, engaged in different costly and value-added activities, which together culminate in a sale. These activities involve coordination among multiple partners, communication forward and backward through the channel, and the participation of payment facilitators and financing entities in addition to those partners handling the physical inventory itself.

Thirdly, keeping a marketing channel running well means recognizing and managing the *interdependence* of channel partners. Different channel members have responsibility for different functions and activities in the marketing channel, and therefore each is dependent on the good offices of all the other channel partners. Given this interdependence, attention must be paid to the possibility of channel conflicts that could disturb channel partners’ incentives to continue performing their assigned roles. Should any such conflicts arise, the judicious application of levers of channel power can help to keep conflict from disrupting the channel’s operation.

This article uses these three elements as core concepts in describing channel design and channel management and implementation in more detail below, after discussing the inherently *strategic* nature of channel design and management.

WHY MARKETING CHANNEL DESIGN AND MANAGEMENT IS STRATEGIC

The design and management of a well-working marketing channel not only takes considerable effort and thought, but it affects the productivity

2 marketing channel strategy

of the rest of the company's marketing efforts as well. An excellent new product idea may enjoy a certain amount of market potential. However, unless the product is distributed appropriately and supported by the efforts of intermediaries, it may fail miserably in the marketplace. Conversely, a well-orchestrated distribution effort can significantly increase the productivity of marketing investments in product design.

Further, the design and execution of a marketing channel is expensive, both at set-up and as an ongoing concern. One analysis estimates that transportation costs average 21% of the cost of goods sold in the United States; border-related trade barriers add a further 44%; and retail and wholesale distribution costs average 55% of the landed cost of goods sold in industrialized countries. These costs combine to a 170% total estimated trade cost above the cost of goods sold.² Clearly, managing the costs of such an effort can have a substantial impact on the product's ultimate sales and profitability in the market.

In addition, developing and running a marketing channel involves the use of other agents and/or companies (the designer's "channel partners") to whom the channel designer allocates important channel responsibilities, yet over whom the channel designer has limited control. This places the channel designer at considerable risk, because of the noncompensatory nature of the channel's work elements. In particular, it is typically not possible to compensate for a channel partner's nonperformance of a designated function by "doing more of" another function over which the channel designer does have control (imagine trying to compensate for a retailer's poor stocking efforts on store shelves by doing more promotion of the product, or shipping more frequently!). The successful channel designer and manager must therefore take account of this risk and foresee and manage any emerging problems; this requires a strategic and long-range focus rather than a tactical, short-term one.

Once established, marketing channel systems tend to be very difficult to dismantle or completely redesign. They involve investments in relationships with sales forces, distributors,

and retailers; negotiations over shelf space or promotional considerations; and the development and adoption of information technology systems that allow the partners to communicate efficiently and quickly. These types of expenditures are not just current costs, but are rightly viewed as investments by the channel designer, with a payoff that is enjoyed for many years into the future (if the relationship is fruitful). The strategic goal is therefore to "do it right the first time."

Because of the positive externalities a well-run channel confers on other marketing efforts of the firm, its expense, the risk inherent in partnering with independent channel members, and the difficulty of redesigning or abandoning an established channel structure; it is therefore clear that proper channel design and management has *strategic* (i.e., long-run and wide-ranging) importance to the overall marketing strategy of the firm.

DEMAND-SIDE INSIGHTS FOR MARKETING CHANNEL DESIGN

The fact that the end-user is the only channel member who *injects money into the channel system* enhances the value of understanding end-user demands and deciding how (and how intensively) to meet them. End-users demand not only products, but also a varied set of services from the channel. In short, it is not only of interest to a consumer *what* s/he buys, but also *how* s/he buys. The types of channel services demanded by consumers are sometimes aptly called "service outputs," identifying these services as the *output* of the work of channel members.

Service outputs vary across different specific channels and end-users. However, a generic list of service outputs includes *lot size, spatial convenience, assortment, speed of shopping/acquisition, and various elements of customer service*.³

Service outputs are inherently good. For example, avoiding shopping hassle, or getting a desired product quickly rather than with a delay, are attractive aspects of the buying process. However, not all consumers value a service output to the same extent. This implies that the delineation of consumer segments for marketing channel design is a function of the *variations* in consumers' service output demands. This is

quite a different concept of segmentation (*see* MARKET SEGMENTATION AND TARGETING) than the one a firm might use when thinking about physical product design; the fact that manufacturers send the same product to market through multiple channels implies that physical product attributes alone are insufficient to determine a product's sales and profit potential.

Thus, even a parity product can be significantly differentiated through the provision of carefully chosen service output levels. The strategic design of the service output bundle to offer along with the product can create *loyal* sales at a *high margin*, because the augmentation of the product with a desired set of service outputs effectively turns a competitive product into a highly differentiated product/service bundle. This is extremely good news for firms selling established lines of mature products that face head-to-head product-attribute competition. Indeed, it is a rare company that can boast more than one or a few truly innovative, unique, patent-protected products that face no current or potential competition. The ability to sell the usual product array depends on the channel's offering of an attractive combination of product and service outputs.

SUPPLY-SIDE AND EFFICIENCY INSIGHTS FOR MARKETING CHANNEL DESIGN

It might seem from the above discussion of service outputs that the channel should seek to provide all valued service outputs in order to prosper in a product-competitive marketplace. Unfortunately, this is not a generally feasible strategy, because of the cost of delivering intensive service output levels. Thus, while a demand-focused approach to marketing channel strategy is critical in developing consumer satisfaction, a complete *profit-maximizing* strategy requires controlling the cost side of the channel as well.

More generally, setting up a marketing channel structure involves addressing the following issues:

- decide what “work” must be done in the channel to generate targeted end-users’ desired service outputs;

- choose channel intermediaries that can reach targeted end-users;
- split the “work” of the channel amongst the chosen channel partners for maximum efficiency (i.e., minimum cost);
- create a reward system that awards adequate compensation for channel members’ work.

Decide what “work” must be done in the channel. The “work” of the channel includes performance of a set of *channel flows*, which are costly functions that must be done in a marketing channel in order to move the product (or service) from the hands of the manufacturer into those of the end-user. A generic list of channel flows includes *physical possession, ownership, promotion, negotiation, financing, risking, ordering, and payment*.⁴

Channel flows are *costly*; they can be done by just one, or by more than one, channel member; and they are done in order to produce desired service outputs. Because of the tension between the value of generating service outputs and the cost of doing so, it is worthwhile to weed out costly but non-value-added functions. One manager of a multinational company, sent to the South American marketplace with a mission of managing distribution costs, found that the company could remove inventory from over half of its stocking distributors in the multicountry region without compromising speed of delivery or product availability. An added benefit was the greater freshness of the product, which was subject to quality degradation over a period of months sitting in inventory. In such cases as this, careful monitoring and control of waste in the performance of channel flows can not only reduce costs, but can in some cases also actually *increase* quality and service provision.

In a specific channel application, the channel manager is urged to customize the generic list of channel flows so that their names and descriptions fit the market concerned. For example, *physical possession* and *ownership* may be fruitfully combined into one flow called *inventory holding* if the holder of product is commonly also its owner. On the other hand, it frequently makes sense to split up the *promotion* flow into multiple separate flows, such as *sales force costs, advertising, sales promotions, and trade show expenses*. Yet other flows, such as *risking*, may be renamed

4 marketing channel strategy

to apply more directly to the business at hand; the cost of risking can be monetized by finding out the cost of an insurance policy to cover a negative outcome in the business, for example. If such is the case, *insurance* may be a better term than *risking* for that business.

Because distribution is so costly, it behooves the channel manager to try to audit the channel in order to understand channel cost levels, who bears them, and how to improve their management. It is often best to examine the accounting and financial systems of channel partners in order to see at what level channel costs can be measured.

When establishing a new channel structure or expanding an existing one, the channel designer must figure out what levels of channel functions need to be done in order to meet target end-users' demands for service outputs. For example, an arts and crafts retailer like Michaels in North America may first recognize that its "casual crafter" consumer segment wants quick availability of a wide range of arts and crafts products, along with project ideas and information on needed supplies and the appropriateness of the suggested project for various age and skill groups. These demands imply a high value for *quick delivery* (i.e., low out-of-stock levels), *assortment and variety*, and *customer service and education*. When Michaels wanted to grow its store network significantly in the 1990s and 2000s, the company realized that these service output demands translated into the need to manage the distribution channel from its suppliers, through its distribution centers, down to its retail stores, to improve the channel's performance on movement, storage, tracking, merchandising, and replenishment of product.⁵

This recognition spurred a multiyear effort on the supply-side of the channel; such initiatives are substantial both in time and money costs. However, without such an effort, significant system growth would be impossible.

Choose channel intermediaries that can reach targeted end-users. Once the channel designer understands the work that needs to be done to generate desired service output levels, the structure of the channel must be determined. Channel structure specifies:

- the *types* of intermediaries to be used; and
- the *specific identity* of each intermediary with whom to partner.

There are many types of intermediaries from which to choose. For example, retailers may be bricks-and-mortar or online (or both); large and multistore or small and mom-and-pop in scope; organized as a franchise business; or broad-line or specialty stores. The manufacturer may use an independent distributor, a value-added reseller, an independent sales representative firm, or a sales broker to help sell its products to downstream buyers. Franchisees, direct selling individual resellers, or multilevel marketing distributor/resellers are alternatives to a standard retailer.

Similarly, once the manufacturer decides what types of intermediaries will be the best partners, it is also necessary to pick the specific partner(s) of each type. For example, when Jenny Craig weight-loss centers decided to augment its client service by offering to send weekly food shipments to them (rather than requiring them to stop in at Jenny Craig retail centers each week to pick up their food), it knew that it needed a third-party delivery partner (thus settling on the *type* of channel intermediary to use). Jenny Craig chose Federal Express as the shipper for its "Jenny Direct" program⁶ – perhaps in a nod to FedEx's reputation for reliability and quick delivery, key service outputs for a consumer who is replacing all of their regular meals with Jenny Craig food.

More generally, in choosing both the *type* and the *specific identity* of its channel partners, a manufacturer generally takes into account the following factors:

- Market coverage (will the potential channel partner help me reach my target end-user segments?)
- Partnership potential and commonality of interest (will the potential channel partner benefit, as I will, from a strong effort to satisfy the target end-user segment?)
- Capability (can the potential channel partner perform the designated channel flows and functions using the right technology and with sufficient skill?).

Split the “work” of the channel amongst the chosen channel partners. With an identified set of channel partners, the channel designer must next decide what elements of the channel workload are to be allocated to which channel member(s). Some channel functions, such as inventory holding, may be performed serially by multiple channel members. Other channel functions, such as promotion or negotiation, could conceivably be focused in the hands of just one channel member. The goal in allocating the work of the channel is to control the total cost of running channel operations, because any unnecessary cost is lost profit to the channel as a whole. Another consideration (discussed further in the section below on channel conflict) is the safeguarding of the channel against the possibility that a channel partner shirks in its performance of channel workflow.

Create a reward system that causes channel members to earn adequate compensation for the work they do. A well-designed and implemented channel creates gross margins (revenue minus cost of goods sold) high enough to cover all channel costs, and to generate profit to each channel member. In order to preserve the incentives of each channel member to continue to do its allotted work and thus perpetuate good channel outcomes, adequate compensation must be awarded. The channel designer can use discounts off list price; functional discounts; spiffs; sales contests; and many other reward mechanisms to directly or indirectly influence the performance of appropriate channel effort.⁷ A detailed analysis of incentive creation in the channel is beyond the scope of this discussion, but in general, good incentives are ones that:

- reward the desired behavior;
- can be recognized by the recipient as tied to the performance of the desired behavior;
- are of sufficiently high value to make it worthwhile to engage in the desired behavior.

Summary of supply-side and efficiency insights for marketing channel design. Note that in order to follow these supply-side suggestions for channel design, the channel designer ideally *knows* what work is in fact done by which channel members,

and how much this work costs. In the real world, this can be a rather aggressive assumption, with neither of these dimensions generally well-known to all participants. However, it may still be possible to *estimate* the costs borne by channel partners, particularly in channel flows for which the channel captain bears a similar cost. For instance, a manufacturer may employ salespeople and thus have an idea of how much it costs its distributor to field a sales force; a channel partner’s warehousing and trucking costs similarly may be estimated by a manufacturer’s own costs in this area.

Ultimately, this suggests the value of developing metrics for the measurement of marketing channel activity and cost levels in order to manage channel costs, communicate the true cost of running the channel to stakeholders, and provide suitably motivational rewards to channel partners.

MARKETING CHANNEL CONFLICT AS A BARRIER TO EFFECTIVE CHANNEL MANAGEMENT

Let us suppose that a well-designed channel structure has in fact been put in place, based on the analyses suggested above on the demand- and supply-sides. Alternatively, we can suppose that a preexisting channel has been analyzed and appropriate incremental changes have been made to close as many gaps on the demand- and supply-sides as possible. Can the channel designer now rest on his/her laurels as the channel seamlessly rolls along in the marketplace?

Unfortunately, the answer is probably no. Persistent *channel conflict* problems beset most channels, even very well-designed ones.⁸ Channel conflict is characterized by one channel member’s behavior which is in opposition to the desires of another channel member, so that the channel members are acting adversarially, rather than cooperatively, vis-à-vis one another. Three general types of channel conflicts are *goal*, *domain*, and *perceptual* (or *perception of reality*) conflict.

Goal conflict. Two channel members experience goal conflict when their objectives or time horizons are incompatible. This form of conflict

is ubiquitous in marketing channels, because of the very fact that channel partners are chosen for their *different* capabilities – not because they are clones of the channel designer. Although all channel partners may well be interested in the same higher-level goal, such as profit maximization, the actions that increase one channel member's profit do not always increase the profit of all channel members. For example, in a franchise channel, investments by the franchisee in better service, more personnel, training, cleanliness, etc. offer benefits to both the franchisee and the franchisor, because the resulting increased sales engender royalty payments to the franchisor as well as net income to the franchisee. However, the franchisee must bear all of these costs itself. Thus, the franchisee does not internalize the full benefits of these investments, and as a result, its goal of maximizing its bottom-line income (which includes those costs) will lead it to spend less on such investments than the franchisor would prefer.

Domain conflict. Domain conflicts refer to disagreements between channel members over either the *responsibilities of*, or the *rights from*, running the channel. Responsibilities include the performance of costly (but value-added) channel flows, and/or the adoption of appropriate technologies for getting the work of the channel done. Rights from running the channel include any direct or indirect financial benefits from participating in the channel. For example, a manufacturer selling B2B products to business customer end-users may use an independent distributor to reach its smaller customers, but reserve larger customers for its in-house sales force (see SALES FORCE STRATEGY). If the distributor invests in good faith in growing a customer relationship, and eventually succeeds in generating high sales from that customer, its “reward” may perversely be the removal of that customer from the distributor's control and reallocation of the customer account to an in-house salesperson. In this all-too-common example, the distributor exerts costly sales and support effort to build the customer account (i.e., takes *responsibility*), and as a result likely perceives a certain *right* to the profits from sales to that account. When the account is taken away, the distributor therefore experiences a

domain conflict with the manufacturer, due to the distributor's belief that this customer was and remains part of the distributor's domain, while the manufacturer believes the customer rightfully belongs to the in-house salesperson.

Perceptual conflict. Perceptual conflicts between channel members occur when they view the same marketplace or set of market stimuli, but perceive them differently. Such conflicts are actually quite common; they can arise when a distributor or retailer has direct contact with end-users and therefore a deep understanding of what end-users want, while the manufacturer may not communicate with them directly. Another common source of perceptual conflict is a difference in norms or culture; what one country's manufacturer views as normal business practices (e.g., working late in the evenings or on weekends) may be viewed as unacceptable in some other countries or cultures. These perceptual differences can lead to conflicts over what constitutes adequate in-market sales effort or what promotional tools are the most effective.

Perceptual conflict is particularly insidious, because by its very nature, it is so hard to detect. The natural tendency is to assume that others see the world the same way that you do, so it can be very hard to recognize that a difference in perception is the root cause of conflict in the channel. If a conflict is not even recognized, there is little chance it will be resolved, much less, anticipated and prevented. Once perceptual conflict is recognized, it has often festered for so long that it is then difficult to deal with.

When any of these conflict sources is strong enough, the entire functioning of the channel may be in jeopardy, because different channel members specialize in the performance of certain subsets of channel functions and flows. A disgruntled channel member who shirks in the performance of its designated channel functions can therefore generate suboptimal service output provision and consumer satisfaction.

While some degree of conflict is to be expected even in a well-working channel, destructive conflict is to be avoided and, if possible, anticipated and prevented before it blossoms. For example, when John Deere began offering lawn tractors through Home Depot – even though it had historically always partnered

with its independent dealer network as its sole route to market – Deere management anticipated the possibility of serious domain conflict, because of the possibility of cannibalization (*see CANNIBALISM*) of dealer sales. To minimize this, Deere only offered entry-level products through Home Depot, while offering the full line through its dealers; as well, Deere dealers became the post-sale service provider for all Home Depot sales, thus offering a revenue stream even on units the dealer itself had not sold, as well as opening an opportunity to up-sell these consumers on accessories and, ultimately, their next lawn tractor. Dealers learned in this process that Home Depot sales did not just cannibalize their sales, but actually expanded the market, attracting new buyers who might never have visited a Deere dealership. Thus, even though adding another route to market is almost always a recipe for increased channel conflict, John Deere's actions prevented the conflict from escalating out of control. Indeed, the addition of the new channel in fact made the legacy channel members – Deere's independent dealers – actually *better off* than before the channel expansion.

In an example like this, the prevention of serious channel conflict involves not only an alert focus on channel partners' attitudes, but also an awareness of the tools available to the channel designer to combat emergent conflict situations. These tools are elements of channel influence or channel power, discussed in the next section.

MARKETING CHANNEL POWER AS A TOOL OF CONFLICT MANAGEMENT

When a channel member uses threats, monetary or nonmonetary rewards, contractual terms, education and expertise, or the value of the brand itself, to align the interests of its partners with its own, that channel member is acting as a channel captain and using sources of *channel power*. *Channel power* is defined as *the ability to induce another channel member to take an action which that channel member would not otherwise have done*.⁹

One conceptualization of power posits that channel member A's power over channel member B is greater, (a) the greater is the *utility*

that A can offer to B, and (b) the *scarcer* is the source of A's utility to B.¹⁰ The concept of scarcity is straightforward: the more A is like a monopolist, the more leverage A can exert over B. For instance, when establishing distribution in a foreign country, it is quite possible that there is only one distributor a manufacturer could use; this distributor wields considerable scarcity power. Meanwhile, the concept of utility simply means that A can offer B something that B values. This "something" could be market access, increased sales, technical expertise, or association with a valued brand-name partner. Further, these two fundamental power sources are complementary inputs to A's total power over B, so that each one enhances the incremental value of the other. A corollary of this is that without at least a modicum of one source of power, the value of the other power source is very low (e.g., with many rivals [i.e., low scarcity], a high level of utility does not afford A a high overall power position; analogously, if A's offer is not of high utility to B, it hardly matters if A is scarce or not).

While this notion of power arising from scarcity and utility is intuitively very appealing, it does not identify a specific typology of utility power sources. Another reference suggests five sources of power that can be thought of as elements of utility power: *coercive*, *reward*, *expertise*, *legitimate*, and *referent*.¹¹ Coercive power is the threat that a benefit will be withheld unless a channel partner behaves as the powerful channel member requests. Reward power, in some sense the converse of coercive power, is the offer of a valued benefit if the channel partner *does* behave as the powerful channel member requests. Expertise power is the ability to share valued knowledge with a channel partner; legitimate power is the perceived right that one channel partner has to influence another; and referent power is the ability to influence another channel member who wants to "identify with" the powerful channel member. By specifying *how* the powerful channel member offers utility to the dependent channel member, this framework identifies what type of influence one channel member has over others.

Importantly, these power sources describe the *potential* of a channel member to exert influence

over another; they do not require the actual exercise of that power. Also of importance is the fact that all channel members wield *some* power; by contrast, if a channel member had literally no power sources at all, it would exit the channel relationship because it could command no profit from the venture. Additionally, while one can audit a channel to evaluate current power positions of each channel member, a company can also make strategic investments in one or several power sources in order to develop its influence over time in its channel relationships. Examples of the accretion of power over time through such strategic investments are the accumulated brand equity (referent power) and operational expertise (expertise power) of franchisor McDonald's, or the reward power inherent in the size of a channel partner like Walmart.

In sum, channel power should be viewed as a *strategic resource* of the firm and investments in channel power should be made judiciously with a view toward the development of *scarce* sources of leverage.

Power can be abused as well as constructively used. In the short run, the use of channel power to improve one's own share of channel profits, to the detriment of other members' profits, may be successful. However, in the long run, this strategy can backfire for at least two reasons. One is that an overly greedy, coercive channel member may literally bankrupt other channel partners and cause them to leave the channel; this leaves the channel with some functions uncovered, which previously were done – essentially at subsidized levels – by the now-defunct channel partner. Ultimately these channel flows will have to be done by some other channel member, who is not likely to agree to subsidize their performance as the earlier channel member did. The other reason an abusive power-wielding strategy can backfire is that eventually, competitors will emerge with whom the “abused” channel partners will be more than happy to partner instead. Eventually, the abusive channel member will find itself without partners, both because its former partners desert it and because its reputation will precede it and make it difficult to form new relationships.

In sum, channel power is the overall term for a set of tools that give a channel member leverage over the actions of other channel members. In

a constructive, well-working channel, power is either latent, or is exercised judiciously to further the channel's goals. In those situations of great power imbalance, the dominant channel member may take advantage of weaker ones in the short run, although in the longer run, such a channel structure is unstable.

CONCLUSION

Channel design and management is an important strategic focus of a successful market-focused company. It involves long-term attention to the demands of end-users not only for the firm's products, but also for the services the channel can offer; the necessity to manage the significant costs that distribution inflicts on the company, through judicious allocation of responsibility for channel flow performance to the chosen members of the channel; and the ability to maintain channel partners' positive incentives and motivations to execute on the specified channel design. These are formidable tasks for any channel designer or manager. However, the upside potential is great, precisely because the challenge is itself great; those who succeed are rewarded with long-standing and loyal relationships with both channel partners and end-user consumers and customers.

ENDNOTES

² Anderson and van Wincoop (2004), p. 691–692. Their definition of “trade cost” includes “all costs incurred in getting a good to a final user other than the marginal cost of producing the good itself: transportation costs (both freight and time costs), policy barriers (tariffs and nontariff barriers), information costs, contract enforcement costs, costs associated with the use of different currencies, legal and regulatory costs, and local distribution costs (wholesale and retail).” The combined effect the authors calculate is $[(1.21 \times 1.44 \times 1.55) - 1] = 1.7$, or a 170 percent increase above production costs. Note that these estimates omit channel promotional costs, which would further increase the total cost estimate.

marketing metrics

Donald R. Lehmann and Dominique M. Hanssens

INTRODUCTION

Marketing metrics are the measurements (typically quantitative) used to assess marketing effort and performance. These fall into three broad categories: capabilities, inputs, and outputs. Capabilities are the strength and resources possessed by an organization. Inputs refer to the effort and budget put into various marketing activities. Outputs refer to the impact of those activities at the customer, product-market, and financial-market levels.

Because marketing encompasses a broad spectrum of activities and capabilities, there is no such thing as “the” marketing metric. Rather, a variety of related measures are available to assess marketing capabilities, marketing inputs (activities), and marketing-sensitive outputs. Further, metrics have different purposes (e.g., descriptive vs. diagnostic vs. evaluative) and time frames (e.g., short- vs. long-run).

One convenient way to organize marketing metrics is in a five-component hierarchy (Figure 1). The first component is the set of capabilities available. The second component is what marketing does (i.e., marketing inputs). The other three components relate to the impact of marketing at the individual (customer), product-market (aggregate customer), and financial-market levels. The hierarchy implies that marketing activities are partially determined by capabilities and influence individuals who, in aggregate, determine product-market results (e.g., sales revenue or market share), which, in turn, drive financial results (including stock price).

Here we first discuss the different types of measurement that are used. We then describe the different levels of measurement. Next we present evidence of how the levels link together, with particular emphasis on the link of marketing activities to aggregate product-market and financial-market results. Here we use the term *products* to refer to either physical goods (e.g., an automobile) or services (e.g., an automobile insurance policy).

Figure 1 A simplified view of marketing metrics.

TYPES OF MEASUREMENT

The term metric implies something can be measured, often quantitatively. Many types of measures are available, but most can be described on two dimensions: whether the measure is *direct* or *indirect* and whether it is *hard* (factual) or *judgmental*. For a concept such as sales revenue, a hard direct measure is available in company records, often as reported in annual reports, 10-Ks or 10-Qs. For more subjective concepts such as attitude (e.g., what customers think), a direct judgment measure is generally required. However, physiological measures may be utilized as well, including most recently fMRI measures designed to determine which regions of the brain have been activated.

In general, judgments involve *survey data*, such as customer ratings, hopefully based on sufficiently large and representative samples. Sometimes customer judgments are estimated or guessed by a firm insider (e.g., a manager or a researcher) or by an external research supplier. This practice is perilous, because individual human judgment is known to be subject to biases.

For some concepts, direct measurement may be either impossible to obtain or unavailable. In these cases, indirect measures are required. Indirect measures come in two types: formative and reflexive. *Formative* measures assess either

| | Direct | Formative | Reflexive |
|-------------------|--|---|---|
| Hard | Concept: sales Measure: units sold | Concept: customer lifetime value Measure: acquisition and retention rate | Concept: printer quality Measure: performance data on resolution, repair record, noise level |
| Internal judgment | Concept: market potential Measure: manager's assessment | Concept: salesforce quality Measure: salesperson performance ratings on timeliness, product knowledge, and customer friendliness | Concept: advertisement quality Measure: manager's assessment of ad likeability clarity, and presentation |
| External judgment | Concept: brand equity Measure: customer ratings of competing brands | Concept: competitive effort Measure: analysts' estimates of planned spending | Concept: software quality Measure: third party rating of software reliability, easy of use, and range of application |

Figure 2 Types of metrics with examples.

(i) determinants or (ii) components of a concept. For example, quantitative and language skills are combined to “form” SAT scores to gauge a student’s preparedness for college. Similarly, *reflexive* multiple questions about a brand (e.g., good–bad, necessary–unnecessary, desirable–undesirable) are used to “reflect” a consumer’s attitude. By averaging the responses, a fairly accurate assessment of overall attitude toward the brand emerges. This assessment averages out slight differences in response to the separate questions as well as random error.

Overall, a direct, hard, and accurate (i.e., unbiased and with low random error included) metric is preferable. When one is not available, which other type of measure to use depends on a combination of availability, cost, and likely accuracy. Figure 2 provides a typology of the different types of measures available. Keeping these distinctions in mind, we now turn to a systematic discussion of the different levels of metrics in marketing.

MARKETING CAPABILITIES

What a firm does and how well it does it are largely a function of what (cap)abilities it has. The broadest capability is the firm’s ability to relate to the outside world in general, and in particular to customers, that is, the firm’s market orientation.

Market orientation has been defined in several different ways. Basically, it is the ability of a

firm to (i) gather information on the outside environment in general and customers in particular; (ii) interpret, analyze, and understand the information, (iii) communicate the information throughout the organization; and (iv) make decisions based on the information and insights gleaned.

Other marketing capabilities relate to the ability of marketing to work with outside constituencies. This includes relations with

1. top management
2. other business functions such as R&D and sales (i.e., interfunctional coordination)
3. suppliers
4. channels
5. government

In addition, a number of capabilities relate to specific skills in the marketing organization, including the ability to

1. assess markets and research customer preferences
2. design and develop new products
3. price and market these products
4. advertise and promote
5. distribute
6. service

Some of these capabilities are readily assessed by simple quantitative measures, while others

are more qualitative and multidimensional in nature. As a result, we need to resort to different types of measurement to adequately represent the entire range of marketing capabilities. We discuss these different types first.

INPUT MEASURES

Input measures describe the effort put into marketing. To an important extent, marketing activities depend on marketing capabilities. These include specific abilities, for example, the ability to create new products, which is related to within-organization knowledge, experience, and access to external resources (e.g., through partnerships and collaborations). They also include broader organizational capabilities such as market orientation (generally considered to be the ability and effectiveness of a company in gathering information about and understanding customers, analyzing customer information and insights, and acting effectively on the analyzed information). Marketing capabilities develop over time as an organization “learns” through experience. While capabilities are critical inputs into decisions about marketing activities (also known as *programs*, *tactics*), here we focus on the activities themselves.

Product development. In addition to the overall R&D budget, which *types of products* and which *technologies or design approaches* (e.g., open source, collaborative development) are followed are key inputs.

Product quality. Products are often described by their *attributes*, which are relevant insofar as they provide tangible or intangible *customer benefits*. In some cases product quality is assessed externally, for example, by third-party comparative *product reviews*.

Service. *Service policies* (e.g., free returns, customer “loaners”) are relevant inputs, as are *hiring and training policies* for customer-facing personnel.

Pricing. *Pricing schedules*, *discounts for quantity purchases*, and *price-matching guarantees* are key pricing decisions and marketing inputs. In the services sector, prices are increasingly expressed as “all-you-can-eat” *subscription prices*, notably

in telecommunications and software. Also popular are *two* (or more) *part tariffs* which consist of a base fee and an incremental per use/product charge when use or purchases exceed a given threshold.

Channels. In addition to the overall budget for channels, *how it is allocated* to various forms of *channel support* (e.g., returns policies, cooperative advertising) is also a relevant input metric.

Personal selling. In addition to sales force budgets, which obviously impact the number of *sales calls made*, *compensation schemes* (e.g., salary vs. commission) and *hiring, training, and support programs* are critical inputs (although often controlled by a separate department within the firm).

Advertising and promotion. As for all activities, overall budget is a key input metric. *How the budget is allocated* is also critical. This is captured in the *media and promotional plans* (often represented in the form of “calendars”). Media include traditional customer touch points such as print, outdoor, direct mail, radio and TV, and the newer, interactive media such as Internet search, Internet display, and digital social networks. It also includes qualitative aspects such as *copy strategy*. Finally, some companies include *public relations* and *corporate sponsorship* efforts under advertising and promotion.

OUTPUT MEASURES: ACTIVITY BASED

How current and potential customers (sometimes called *prospects*) respond to marketing activities is the first, and critical, indication of the effectiveness of marketing activities. Different activities have different initial impacts and hence measures of effectiveness. For example, for channels, *how many channels carry the product* (often assessed in packaged goods as percent ACV, the percent of all commodity volume sold by outlets that carry the firm’s product(s)) is a basic measure. In addition, the (retail) *support they give the product* (e.g., featured in ads, displayed prominently, given multiple shelf facings, restocked regularly) is the result of both company efforts and customer demand. For a company with multiple stores (or franchisees), both the *number of*

4 marketing metrics

stores and the *sales and margin per store* (also known as *same-store sales*) are critical metrics, since their product is total sales and margin respectively.

A more complete list of metrics reflecting the direct result of marketing activities appears in Table 1. Several of these results are of an *intermediate* nature, that is, they serve the purpose of assessing direct impact, but are not end goals in and of themselves. The link between intermediate metrics and overall business and financial performance is discussed later in the article.

OUTPUT MEASURES: FINAL CUSTOMERS/USERS

Because customers are critical to the market system, we discuss metrics related to them in more detail. Customer metrics can be described in a five-level hierarchy:

1. *Awareness*: The most basic level is awareness, that is, knowing that a product or brand exists and what it does or is used for. Both unaided (e.g., “which auto insurance providers have you heard of?”) and aided (e.g., “which of the following auto insurance providers have you heard of?”) *recall* are used to measure awareness. *Knowledge* about basic features is also a critical metric.
2. *Associations*: At least two categories of associations with a product (or brand) exist. The first is more factual and relates to *product performance* (e.g., the car handles well, gets good gas mileage, is easy to repair). The second is more psychological and *image based* and relates to *design* (e.g., the car is stylish), *users* (e.g., the car is for twenty-somethings), or *emotions* (e.g., the car confers status), as well as *personality* (e.g., the car is “macho”).
3. *Attitude/Preference*: This level of metric assesses whether customers *like* the product, often measured on 0–100 scales or constant sum scales where points are divided among alternatives to reflect relative preference. Related measures are *intention to buy* and *willingness to pay* (WTP: the amount the customer is willing to pay for the product).
4. *Attachment: Loyalty* (or in the extreme, addiction) to a product is a key to repeat

business, and hence future profits. The *extra amount one is willing to pay* for a particular alternative is one measure of loyalty, as is the *repeat purchase rate* (typically used in consumer goods businesses) and the *retention rate* (typically used in service businesses).

5. *Activity*: Customer *word of mouth* has long been an important manifestation of feelings toward a brand. This type of activity is also manifested in membership in product/brand groups (e.g., brand communities on the Web). Monitoring positive and negative comments is one way to keep track of this. A popular but controversial measure of activity is the *net-promoter score*, the number of people who would strongly and positively recommend a product or brand minus the number who would give a strong negative recommendation.

In addition to the metrics already discussed, four others are particularly important. While the first one is widely known (who has not been asked to fill out a satisfaction survey?), the others are also worth monitoring.

1. *Satisfaction*: Both *transaction satisfaction* (customer satisfaction with a particular transaction) and *cumulative satisfaction* are critical metrics. Event (transaction) satisfaction builds overall satisfaction, attitude, and intention to repurchase. Satisfaction depends on both the actual performance of a product and how well that performance compares to the customer’s expectations of performance, the so-called “gap.”
2. *Consideration*: A key metric is whether a customer is *willing to consider* purchasing a product or brand either actively (e.g., “what brands of tennis racquet would you consider purchasing?”) or as a substitute (e.g., “if your favorite brand of paper towels—say, Bounty—were out of stock, would you consider buying Scott towels?” or “if Scott were on sale and Bounty was not, would you buy Scott?”). Interestingly, whether your brand is in a consideration set and how many other alternatives are in it as well gives an approximate prediction of market share as 1 (if your brand is in the set) divided by the total number of brands in the

Table 1 Specific marketing activity metrics.

| <i>Activity</i> | <i>Input Measures</i> | <i>Output Measures</i> |
|---------------------|--------------------------|--|
| Advertising | Media plan | Awareness |
| — | Copy | Attitude toward the ad |
| — | — | Attitude toward the product |
| — | — | Perceptions of the product |
| — | — | Reach (% who were exposed) |
| — | — | Frequency (average number of times people see the advertisement) |
| — | — | Cost per thousand (CPM) |
| Channels | Targeted outlets | % stores carrying |
| — | — | Retail support (features, displays) |
| Internet | Website design | Visits |
| — | Capacity | Pageviews |
| — | — | Click-throughs |
| — | — | Sales |
| — | — | Orders |
| Pricing | Base price | Price paid |
| — | Price schedule | Price premium |
| — | Price discounts | — |
| Promotions | Deal timing | Sales (percent) bought on deal |
| — | Depth of discount | Incremental sales |
| — | Method of distribution | Net profit: short run |
| Product development | Technology focus | Sales |
| — | Product focus | % sales from new products |
| Sales force | Time spent | Orders taken |
| — | Allocation of effort | Sales |
| — | Compensation method | Sales versus quota |
| — | Training | — |
| Service | Returns policy | Service satisfaction |
| — | Service center resources | Time to service |
| Overall strategy | Targeting | Sales |
| — | Positioning | Share |
| — | — | Profit/Margin |

- set. For example, if there are four brands in the set including yours, the probability a person will choose your brand is about $1/4$.
3. *Confidence*: While attitude measures generally focus on a single estimate of how well a customer likes a product, how strongly they hold their opinions (i.e., their level of certainty) is also relevant, and correlates highly with actual choice.
4. *Brand value/equity*: Several commercial “mind-set” measures of the value of a brand to consumers are available. Most of their content is captured by the “5

As” (awareness, association, attitude, attachment, activity) discussed previously.

These final customer metrics are also intermediate output measures. For example, good service may enhance customer satisfaction, but this satisfaction in and of itself does not add value to the company. It needs to be translated to a metric of business or financial performance.

PRODUCT-MARKET METRICS

While metrics that assess customer attitudes provide primarily diagnostic information (i.e.,

6 marketing metrics

why people do, or do not, buy a product), product-market measures effectively are evaluative (i.e., tell us overall how we are doing). Note that the metrics used to evaluate specific marketing activities include many such product-market-level measures.

Individual (customer)-level product-market metrics. For decades people in direct marketing have used their databases to assess their business performance with individual customers and prospects. Traditionally, they have followed an RFM approach: How *recently* a customer has made a purchase, how *frequently* they purchase (e.g., six times a year), and what the *monetary value* of their purchases is. The more recent and frequent the purchase and the greater the monetary value (preferably measured by margin rather than revenue), the more valuable is the customer. Effective marketing activities should increase at least one of these metrics.

More recently, the focus has shifted to assessing the value of a customer over his or her lifetime, also known as *customer lifetime value (CLV)*. A current customer's future CLV is basically the total expected value of the net revenue (i.e., margin) received from a customer over his or her lifetime. In the special case, where the margin and retention rates are constant, a customer's CLV is $CLV = \sum_{t=1}^{\infty} mr^t \left(\frac{1}{1+i}\right)^t = m \frac{r}{1+i-r}$. In this formula, r is the retention rate, that is, the probability that a customer in period $t-1$ remains a customer in period t , m is the marginal profit in a period from transactions with the customer, and i is the discount rate (typically 10–12%). Analyzing CLV at the individual customer level requires transaction records, something direct marketers (using mail, phone, internet) typically have available.

Overall (aggregate) product-market-level metrics. Overall performance is most typically measured in terms of *sales*, *share*, or *profits/margin*. Table 2 provides a list of common product-market metrics. The first group of aggregate metrics (sales, share, etc.) basically assesses sales and sales revenue (i.e., top-line measures), and are often contrasted with planned and/or expected results.

Table 2 Product-market-level output measures.

| | |
|------------------------------------|--|
| Individual-Customer Level: | |
| Recency | |
| Frequency | |
| Monetary value | |
| Retention | |
| Margin | |
| Customer lifetime value (CLV) | |
| Aggregate Market Level: | |
| Sales (unit, dollar) | |
| Share | |
| Share of wallet | |
| Penetration/% buying | |
| Price | |
| Margin | |
| Price sensitivity (elasticity) | |
| Marketing sensitivity (elasticity) | |
| Aggregate customer-based | |
| Repeat rate | |
| Retention rate | |
| Margin per customer | |
| Customer acquisition | |
| Customer equity | |
| Brand | |
| Price premium | |
| Volume premium | |
| Revenue premium | |
| New product introductions | |
| Trial or adoption rate | |
| Repeat rate | |
| Volume | |
| Growth pattern | |

The second group of metrics focus on the customer level. In aggregate, there are only three ways to increase revenue:

1. increase the retention rate of existing customers,
2. increase the margin (via up-selling or cross-selling) per customer, or
3. acquire new customers.

Both absolute values and relative values vis-a-vis competitors are worth monitoring. As an example, if two competing software providers A (the market leader) and B (a smaller player) are equally successful in acquiring new

customers, but B retains a higher fraction of its existing subscribers, then B will eventually overtake A.

If we take the sum of a firm's customers' individual CLVs, we obtain an important aggregate performance metric called *customer equity*; see Gupta and Lehmann (2005) for a detailed coverage. Like CLV, customer equity is a forward-looking metric that emphasizes long-term profitability as opposed to mere size. For example, a firm with a larger market share may have a smaller customer equity because its customers are not as profitable as those of a smaller competitor. Customer equity is related to a firm's stock price, as is discussed later in the article.

The final group of metrics assesses the relative performance of a brand. A brand with positive equity (i.e., one which is liked) can take advantage of this equity by virtue of a price premium (they can charge more than a generic competitor) or by virtue of extra sales (they have higher demand than the generic competitor). By combining these two sources of competitive advantage, we may compute the brand's *revenue premium* (the extra revenue a brand receives vs. an equivalent generic product), which is a useful measure of the value of a brand.

ASSESSING THE LINK BETWEEN MARKETING ACTIVITIES AND PRODUCT-MARKET METRICS

In order to make product-market metrics useful in marketing decision making, we must know how they respond to various marketing inputs or activities. Similarly, changes in intermediate performance metrics need to be converted to financial performance results in order to make them useful for resource allocation decisions. As different metrics can have widely different scales (for example, units, dollars, percentages, attitude ratings), we need a uniform linkage metric that enables comparison across different marketing inputs and outputs.

A classic (and very useful) measure of the effectiveness of an activity, or the business importance of an intermediate metric, is its *elasticity*. The elasticity of an activity is the percent change in a criterion variable Y (e.g., sales), which results from a given percent change in

the activity X , written algebraically as: $\frac{\Delta Y/Y}{\Delta X/X} = \left(\frac{\Delta Y}{\Delta X}\right) \left(\frac{X}{Y}\right)$. Elasticities have the following desirable properties:

1. They are scale-free. For example, expressing marketing budgets in dollars, in thousands of dollars, or in Euros does not change their sales elasticities.
2. 'Percent change' language is easily understood by managers and researchers alike, and provides a useful input to marketing planning.
3. They represent three very different and strategically important response scenarios:
 - diminishing returns, that is, elasticities between 0 and 1 in absolute value. When diminishing returns are present, marketing resources have to be allocated carefully, as overspending may result in substantial profit loss. Most marketing inputs (e.g., advertising) are subject to diminishing returns.
 - increasing returns, that is, elasticities greater than 1 in absolute value. These often provide exceptional revenue generating opportunities, but are relatively rare.
 - no returns, that is, elasticities are zero, an indication that the activity produces a dead-weight loss.

While elasticities can be estimated subjectively, it is preferable to estimate them from relevant (e.g., past or comparable situation) data, for example via multiple regression analysis. This approach is sometimes referred to as *marketing mix modeling* or *market response modeling*; see Leeflang *et al.* (2000) or Hanssens, Parsons, and Schultz (2001) for detailed coverage. When X refers to price, you ideally want a small "up" elasticity (sales do not decrease much if you raise price) and a big "down" one (if you do cut price, you get a large increase in sales volume). That tends to be the case for strong brands, as opposed to their unbranded or weakly branded competitors. When X refers to a marketing budget item such as advertising or trade support, you ideally want the elasticity to be strong enough that it justifies the spending level. The most typical scenario is shown in Figure 3: the *sales response*

Figure 3 Typical sales and profit responses of marketing spending.

curve is concave, but the *profit response curve* is an inverted U. Knowing the shapes of these curves helps managers realize that higher revenues from more aggressive marketing do not automatically result in higher profits. The response curves also depend on the presence or absence of *competitive reaction*, and may be different in the short run versus the long run.

Interestingly, sales elasticities tend to be fairly consistent for the same marketing input across different business settings. Researchers have been able to derive “empirical generalizations” from many replications and these provide a starting point for subjective elasticity estimates, as well as a way to check the reasonableness of any given set of projections. We summarize below a few of these generalizations and refer to Hanssens (2009) for a more complete list.

1. *Advertising*: The short-term sales elasticity (impact on sales) of media advertising tends to be small (e.g., .01–0.03) for increases in spending for mature products that provide no new information about the product. The elasticities are more substantial (e.g., around 0.30) for ads for new products or for genuinely new uses of existing products. The long-run (total) effect of advertising has been found to be about 2 times the short-run effect for many consumer products.
2. *Personal selling*: The elasticity of sales calls is much higher than that of advertising, averaging up to 0.35. Like advertising, personal selling tends to be more impactful in the earlier stages of the product lifecycle.
3. *Pricing*: Estimating pricing elasticities is complicated by the fact that competition

responds rapidly to price changes, which makes it difficult to disentangle the various influences. Nonetheless, price-level elasticities tend to be in the range of -1 to -3 , with an average of -2.6 in competitive markets. Elasticities are much lower for monopolies or genuinely new products.

NEW-PRODUCT PERFORMANCE

New products play a critical role in many businesses and early detection of likely success or failure is important. Beyond mind-set measures such as awareness and attitude, the first critical market level metric is *trial*. For frequently purchased products, *repeat* purchases are crucial for a product to succeed, (i.e., *adoption* occurs only for those who repeat buy a product) as is *volume per customer*. For durables (as well as for consumer products), the eventual number that adopt a product, that is, its *penetration level*, is crucial. In addition, the sales *growth rate* is important, because future earnings, once discounted to present value, become less relevant. Slow sales growth means future increases in sales will have less value.

FINANCIAL METRICS

Financial performance. Financial performance metrics (Table 3) are important if for no other reason than that accounting and finance professionals (e.g., the Chief Financial Officer or CFO) think in terms of them. Basic outcome measures include *revenue*, *net revenue*, and *cash*

Table 3 Financial metrics.

| |
|----------------------|
| Performance |
| Revenue |
| Net revenue |
| Cash flow |
| Return on sales |
| Return on investment |
| Volume variance |
| Price variance |
| Valuation |
| Stock price |
| Stock return |
| Tobin's q |

flow. Other measures assess the effectiveness with which resources (marketing budgets) are being deployed, that is, *return on spending (investment)*. Pressure to demonstrate financial effectiveness is strong.

Other measures compare performance to planned levels, including the *volume variance*, that is, “actual versus planned unit sales,” and the *price variance*, that is, the actual versus planned average price paid. Note these two are related because lowering price increases volume. Still there is some diagnostic value in learning whether a revenue shortfall (or overage) is due to reduced sales volume or a lower price. Albers (1998) expands these diagnostics to the other elements of the marketing mix.

Financial valuation. Linking marketing activities (e.g., new-product introductions) or assets (e.g., customer satisfaction, brand equity) to *stock price* is important but difficult. These links have been researched recently see Srinivasan and Hanssens (2009) for an extensive review. The basic logic underlying this work is the “efficient market hypothesis,” which suggests that the stock market takes into account the future earnings performance of a firm and discounts it to present value to arrive at the price of a stock. (While few people believe all markets are instantaneously efficient in the near term, it seems reasonable to argue that stock markets do take into account future earnings.) As a result, (unexpected) changes in marketing actions can lead to unexpected changes in net revenue,

which impacts stock value. While it is unreasonable to expect to detect the link between a minor tactical marketing activity and stock price (e.g., changing “vegetable soup/light” to “light vegetable soup”), there is evidence that more strategic marketing activities do impact stock price. Examples include new-product introductions and announcements, changes in advertising budgets, and customer satisfaction.

Note that for privately held firms or for nonprofits, stock price maximization is typically not the goal. For churches, for example, membership and attendance may be the key long-term performance metrics.

SUMMARY

Many metrics are available to assess marketing performance, ranging from individual mind-set measures (awareness, associations, etc.) to changes in stock price. Measuring and striving to improve them can lead to improved business performance. Several caveats, however, apply:

Blind use of a few metrics can have unintended consequences: Use of a few key metrics can lead to efforts devoted to improving the metrics versus overall company performance. Further, it encourages “gaming the system,” and runs the risk of encouraging manipulation of the metrics.

The distinction between forward- and backward-looking metrics is important: Most financial performance metrics are backward looking, that is, they describe what was, for example, sales or market share. More important for management are forward-looking metrics that are leading indicators of future performance, such as brand equity, customer satisfaction, and CLV.

Levels are interesting; changes and relative values are predictive: Knowing that, say, 80% of a firm’s customers are satisfied is interesting. Knowing how this number compares to the competition, and whether it is increasing or decreasing, is important. More broadly, profitable revenue growth, in general, is a key objective. Among other things, it is reflected in a firm’s price/earnings (P/E) ratio and stock price.

Means versus variances and customer heterogeneity: Both the level of variables and their variances matter. In particular, different segments of customers may have different views of a brand or a product, and these differences may be obscured in overall averages. Marketing metrics should be defined at appropriate segmentation levels, which, in some cases, means at the individual-customer level.

marketing mix

Gerald Albaum

The success of any MARKETING STRATEGY depends largely upon how the various marketing methods or tools are used by a firm to achieve a predetermined goal/objective. The planned and coordinated combination of such methods or tools to achieve goals and objectives is called the *marketing mix*, which is embodied in what is known as the firm's marketing program (Albaum and Duerr, 2008, p. 688). Thus, marketing strategy is reflected in how a firm integrates the elements of the marketing mix into the marketing program.

The marketing mix includes four major activities – product (*see* PRODUCT CATEGORY), price (*see* PRICING STRATEGY), distribution (*see* MULTICHANNEL MARKETING; MARKETING CHANNEL STRATEGY), and promotion (*see* INTEGRATED MARKETING COMMUNICATION STRATEGY; COMMUNICATIONS BUDGETING; SALES FORCE STRATEGY) – that a firm controls to meet the needs of customers (*see* CUSTOMER ANALYSIS; CUSTOMER SATISFACTION/DISSATISFACTION) within its target market (Pride and Ferrell, 2010, p. 5). A central feature is that it is built around the customer (or consumer). That is, the marketing program and the marketing mix should be formulated with the interests and needs of the consumer in mind. It must be structured in such a way that it integrates the customer into the company and leads to the creation and maintenance of a solid relationship between the company and the customer (*see* CUSTOMER RELATIONSHIP MANAGEMENT). A firm operating in this manner is said to be market driven or following the practice of MARKET ORIENTATION, and is concerned with what the consumer will buy that can be made profitably. The marketing mix is what makes all this happen. This is as true for international (including export) marketing (*see* GLOBAL MARKETING STRATEGY) programs and strategies as it is for domestic marketing programs and strategies.

In the last decade there have been a number of studies about various aspects of the concept

of the marketing mix. A couple of representative examples are discussed below.

The choice of the elements of the marketing mix, or marketing tactics, is influenced by the firm's external environment. There are times when this environment can be complex and turbulent. As complexity increases, a manager's ability to plan, predict, and understand becomes harder, thus leading to more change. Turbulence involves fast and unexpected change in the environment, leading to greater uncertainty. What all this means is that in order for marketing success to occur in a turbulent environment, a different approach to the marketing mix is required. Mason and Staude (2009) propose a marketing mix tactics model based on chaos and complexity theories that can be used for success in a complex and turbulent environment.

Chen and Green (2009) studied the relationships between the marketing mix and customer-based PERCEPTION OF BRAND EQUITY between male and female shoppers in hypermarkets in Taiwan. Differences were observed between genders, with females scoring higher than males on customer-based brand equity. An earlier study of selected marketing mix elements and brand equity was reported by Yoo, Donthu and Lee (2000), who found how specific mix elements used can be either brand-building (high advertising spending) or brand harming (frequent use of price promotions).

Advances in analytical approaches to data analysis and the proliferation of media and channels of distribution have direct implications for the marketing mix and how it is managed in a company. Recent developments in modeling market response to marketing mix variables with specific emphasis on improving marketing resource allocation, given the above developments, is covered by Kerin and O'Regan (2008).

The concept of the marketing mix has stood the test of time since it was first popularized by McCarthy (1960) as the 4 P's! The mix elements are interrelated and interdependent, and can be substitutes and/or complements for each other. Industry has embraced the concept. For example, the trade publication *LP Gas Magazine* in early 2009 introduced a new section into its publication titled *Marketing Mix* (LP Gas, 2009, p. 39).

marketing strategy models

Venkatesh Shankar

INTRODUCTION

Marketing strategy models are being increasingly developed and used by academics and practitioners worldwide. Be it a model for new-product forecasting or a model for allocating marketing resources, marketing strategy models form the basis for strategic marketing decisions.

A marketing model is a mathematical representation of a marketing phenomenon. A marketing strategy model is a marketing model focused on a strategic marketing problem (Shankar, 2008a). The main purpose of a marketing strategy model is to develop tools or insights for the formulation of marketing strategies.

For the purpose of this article, marketing strategy topics are viewed as those that exhibit the following characteristics: (i) the relevant marketing strategy decision variable has long-term consequences; (ii) the marketing strategy topic comes under the decision purview of senior marketing executives (e.g., chief marketing officer, vice president – marketing); and (iii) decisions relating to the marketing strategy topic involve a substantial amount of marketing resources (Shankar, 2008b).

Marketing strategy models can be classified into three types: descriptive models, normative models, and predictive models. A *descriptive model* is one that explains at least one variable (O) (e.g., sales, market share, abnormal financial returns) as a function of one or more marketing strategy variables (MV) (e.g., order of market entry, advertising spending) through a general equation such as $O = f(MV)$, where f is a linear or nonlinear function. A descriptive marketing strategy model may comprise one or more equations (system of equations). Typically, descriptive models are associative in nature; that is, a typical descriptive model simply states that two variables (e.g., a marketing strategy variable and sales) are correlated. Some descriptive models go beyond correlational relationships to explain a marketing phenomenon in terms of one or more marketing strategic variables causing the observed outcome. Descriptive models are typically calibrated (the parameters specifying

relationships are estimated) using empirical data. An example of a descriptive model is a model of new-product spending by Gatignon, Weitz, and Bansal (1990). Advanced descriptive models include Bayesian models (see Rossi, Allenby, and McCullogh 2007).

A *normative marketing strategy model* is a model that offers prescriptions or guidelines to managers on what strategic decisions should be undertaken under specified conditions. For example, a normative model of market entry would provide managers with the recommended order and time of entry into a market for a given set of conditions. Typically, normative models are developed using optimization approaches from the operations research (OR) discipline or game theoretic principles. Usually, normative models are purely analytical in nature. That is, they are based on mathematical formulations, derivations, and expressions, and are not estimated using empirical data. However, some normative models are based on empirical data. A marketing allocation strategy model is an example of a normative model (Shankar, 1997).

A *predictive model* is one whose main purpose is to predict a future outcome. The future outcome could be strategically important to the firm and may or may not be a function of marketing strategy variables. A sales forecasting model is one such predictive marketing strategy model because sales forecasts are critical to the top-line performance of many companies. An example of a predictive model not based on a marketing strategy decision variable is the Bass (1969) model. This model predicts periodic sales as a function of cumulative sales. An example of a sales forecasting model that is based on marketing strategy variables is the channel sales forecasting model by Divakar, Ratchford, and Shankar (2005).

A typical marketing strategy model exhibits the following characteristics. (i) it contains important marketing outcome variable(s) and predictor marketing strategy variable(s); (ii) it comprises well-specified functional form(s) of the relationship between marketing strategy variable(s) and marketing outcome variables, based on a theoretical mechanism; and (iii) it is reasonably robust to different plausible real-world conditions.

There are three basic types of empirical descriptive models depending on the nature of data used to estimate the model. If the data are cross sectional (e.g., from multiple firms at a single point in time), then cross-sectional models are most appropriate. If the data are longitudinal (e.g., from the same firm at different points in time), then time series models are most relevant (Dekimpe and Hanssens, 1999; Hamilton, 1994). If the data are both cross sectional and longitudinal (i.e., for a set of firms for multiple periods), then time series cross-sectional models are most commonly used. A special case of time series cross-sectional model is the panel data model, in which data come from the same set of cross-sectional units over time. Two types of panels exist. A balanced panel is one in which the time periods are the same for each cross-sectional unit. An unbalanced panel is a panel in which the time periods for some of the cross-sectional units are different.

Depending on the scale of the dependent variable, a marketing strategy model could be a regression model or a limited dependent variable (quantal) model. While most marketing strategy models are regression based, some models are limited dependent variable models, an example of which is a model of determinants of competitor response time by Bowman and Gatignon (1995).

Empirical industrial organization models are those that focus on marketing strategy decisions through analysis of both demand (e.g., sales, market share) and supply (e.g., pricing strategy, marketing allocation strategy) functions (Tirole, 1988). Typically, there is at least one demand equation and one supply equation. The demand and supply equations are derived from utility maximization principles and are hence structural in nature (Chintagunta *et al.*, 2006). In a marketing strategy context, the models are typically based on game theoretic analysis (Berry, Levinsohn, and Pakes, 1995; Shankar, 1997).

Consistent with the view of marketing strategy topics outlined earlier, marketing strategy decisions can be classified into three major topic areas: (i) new-product development (NPD) and product management strategy, (ii) market entry and growth strategy, and (iii) defensive or reaction strategy. (Table 1) Marketing strategy models relating to other topics such as customer

equity (Reinartz and Kumar, 2003), brand equity (Shankar, Azar, and Fuller, 2008), and network effects (Shankar and Bayus, 2003), are important but are not discussed as they are outside the scope of this article. For detailed discussions on a more comprehensive set of marketing models, see Eliashberg and Lilien (1993), Hanssens, Parsons, and Schultz (2001), and Lilien, Kotler, and Moorthy (1992). Game theoretic models exist for analyzing competition in strategic marketing variables such as order and sequence of market entry, positioning, and defensive reactions, and in strategic levels of product, price, distribution channels, and advertising (for a detailed review, see Moorthy, 1985). For more details (see COMPETITIVE ANALYSIS).

The rest of the article is organized as follows. The basics of game theoretic models are summarized in the next section. Marketing strategy models under each topic are described in each of the remaining sections. Each section discusses the models used in representative studies, summarizes the findings from these studies, and outlines the strengths and weaknesses of the models.

GAME THEORETIC MODELS

Game theoretic models are being increasingly used for marketing strategy analysis. These models analyze strategic interactions between players in marketing strategy variables and predict market outcomes. In a marketing game theoretic model, the players (firms and/or consumers) play a noncooperative game in which they choose their marketing strategies. A firm's strategy is a complete specification of its actions under all possible contingent scenarios in the game framework.

The main assumptions of game theoretic models are that the players are rational and intelligent. In the context of firm marketing strategy, rationality refers to the firm's maximization of subjective expected utility (profits) and intelligence refers to the firm's awareness that its competitors are rational. In a game theoretic model, the goal is to identify the existence of equilibrium and solve for equilibrium strategies by the players. An equilibrium condition is represented by strategies from which

Table 1 Summary of selected marketing strategy models.

| <i>Paper</i> | <i>Model Type</i> | <i>Data</i> | <i>Key Findings/Contribution</i> | <i>Key Limitations</i> |
|--|--------------------------------------|--|--|--|
| New-Product Development and Product Management Strategy | | | | |
| Sorescu, Chandy, and Prabhu (2003) | Abnormal financial returns model | 255 innovations from 66 firms during 1991–2000 from NDA pipeline | Dominant pharmaceutical firms introduce more radical innovations. Financial value of radical innovation increases significantly with marketing and technology support. | Nondominant firms may not have resources to spend simultaneously on multiple innovative ideas. |
| Grewal <i>et al.</i> (2008) | Regression model | 308 firms in the Pharmaprojects database | Both early- and late-stage products-dominated portfolios are significantly positively associated with their financial values. | R&D intensity, advertising expenditures, and growth rate were omitted. Cross-sectional analysis had its drawbacks. |
| Market Entry and Growth Strategy | | | | |
| Gatignon, Weitz, and Bansal (1990) | Regression model | 68 brands of new drugs from 39 firms during 1978–82 | Resources drive the level of launch communication efforts. Market growth rate moderates the effectiveness of detailing on market share. | The dynamics of competition or longitudinal data were not studied. The interaction of firm capabilities with environment was not considered. |
| Shankar, Carpenter, and Krishnamurthy (1998) | Trial, repeat generalized Bass model | 13 brands from two categories from IMS Health database | Innovative late movers can enjoy advantage through greater market potential, higher repeat rate, and faster growth than the pioneer. They can also slow the growth and marketing effectiveness of the pioneer. | Only two product categories were analyzed. |
| Shankar, Carpenter, and Krishnamurthy (1999) | Dynamic sales response model | IMS Health data on 29 brands from six categories | Growth-state entrants reach asymptotic sales faster than pioneers or mature-stage entrants. Buyers are more responsive to pioneer's marketing spending. Mature-stage entrants are most disadvantaged. | The categories covered did not have failed brands. |

Table 1 (continued).

| <i>Paper</i> | <i>Model Type</i> | <i>Data</i> | <i>Key Findings/Contribution</i> | <i>Key Limitations</i> |
|---------------------------------------|---|---|--|---|
| Shankar (1999) | Rational expectations simultaneous equation model | 23 new brands in six markets | New-product introduction spending is significantly influenced by incumbent reaction. | The product categories did not exhibit market exits. |
| Fischer, Shankar, and Clement (2005) | Relative market share model | 73 brands in two categories from eight European markets | Late movers can reduce order of entry penalty by entering large countries in a sequential manner. | The US market was not included in the data. |
| Defensive Strategy | | | | |
| Gatignon, Anderson, and Helsen (1989) | Regression model | Two new entries in the OTC-gyn category | Competitors retaliate (accommodate) with their most (least) effective marketing weapons. | Incumbent elasticities were not significantly altered by the new entrant. Uncertainty and the firm's perceptions were not included in analysis. |
| Shankar (1997) | New empirical industrial organization model | A large drug product category | Pioneers who adopt a follower (leader) role in a marketing mix variable in a static (growing) market and whose elasticity is decreased (increased) should accommodate (retaliate) against a new entry. Pioneers should accommodate (retaliate) with its competitively low (high) elastic variable. | Repositioning reactions were not considered. The response function was decoupled. |
| Shankar (1999) | Relative spending model | 59 incumbent responses to entries in six categories | Higher spending by a new brand and multimarket contact result in weaker incumbent response. | Product and pricing reactions were not studied. |

NDA, new drug application.

no competitor has an incentive to unilaterally deviate from its strategy.

Formulation and analysis of a game theoretic model involves many steps. The first step is to specify such rules of the game as the number of competitors, the set of feasible strategies or decision variable(s), the utility or profit

function, the number of periods (single or multi-period), whether one competitor is a leader or follower in the decision variable(s), and the information known to the competitors at different stages of the game. Some information such as which competitor moves first is known to all the competitors and is known as *common knowledge*.

If all information is common knowledge, then the game is known as a game with *complete information*. Some information such as manufacturing cost can be known to the focal firm but not to its competitors and are, therefore, labeled *private information*. In this case, some rules of the game are not common knowledge, so this game is known as a game with *incomplete information*.

Games can exhibit symmetric or asymmetric information. In the case of information symmetry, all competitors are similar in their information knowledge. In the case of information asymmetry, competitor X may have information on a variable (say cost) about competitor Y, but competitor Y may not have the information on the same variable about competitor X.

Different types of game theoretic models exist for analyzing different conditions. For example, a game in which one competitor is a leader and another is a follower is known as a *Stackelberg game* and the corresponding equilibrium is known as the *Stackelberg equilibrium*. In contrast, the equilibrium corresponding to a game in which all competitors move simultaneously is known as the *Nash equilibrium*. For the possible existence of both these equilibria, see Shankar (1997).

While much of game theoretic analysis is based on noncooperative interdependence among competitors, cooperative game theory examines the collusive behavior of firms. The predictions of game theory models can be tested through empirical analysis. While game theoretic models are powerful tools for competitive analysis, they suffer from limitations such as unrealistic assumptions about the game and the inability to capture real-world phenomenon through tractable models.

NEW-PRODUCT DEVELOPMENT AND PRODUCT MANAGEMENT STRATEGY MODELS

Models on new-product development strategy include those on the cost and returns to spending on new-product development. Product management strategy models range from product selection models to product portfolio models. Although a number of models exist on this topic, only two are reviewed to offer a sample

of relevant marketing strategy issues. Sorescu, Chandy, and Prabhu (2003) estimate a descriptive regression model of financial returns to radical innovations by pharmaceutical companies. They find that dominant firms introduce more radical innovations even after accounting for the source of the innovation (in-house vs acquired) and that they also introduce more market breakthrough and technological breakthrough innovations. Their results show that the financial value of a radical innovation significantly increases with greater product marketing, technology support, and product scope, and that it is significantly greater than the financial value of market breakthrough or technological breakthrough, but there is no significant difference between the values of market breakthrough and technological breakthrough innovations. Their model, however, does not address the risks associated with such innovations as well as with incremental innovations. Firms are interested in such issues as they decide on the number and mix of products in their NPD pipeline.

Grewal *et al.* (2008) relate the choice of products in the product portfolio by the stage of new-product development to the financial value of the portfolio. Their descriptive regression model has Tobin's Q as a function of net income, current ratio, debt-to-equity ratio, competitor's new-product portfolio market potential, the firm's new-product portfolio market potential, number of product categories, and cross-category variance. They estimate this model with data from the product portfolios of 308 firms in the *PharmaProjects* database.

They find empirical support for both early- and late-stage products-dominated portfolios to be significantly and positively associated with their financial values. Their model, however, does not include potentially relevant variables such as research and development (R&D) intensity, advertising expenditures, and growth rate due to nonavailability of data. Furthermore, the cross-sectional model that they use may not be able to fully capture the differences in effects as products move from one stage to the next stage over time.

Other models on this topic include those on new product alliances (Kalaighnam, Shankar, and Varadarajan, 2007), new-product announcements and preannouncements (Sorescu, Shankar

and Kushwaha, 2007), and product line strategy (Shankar, 2006).

MARKET ENTRY AND GROWTH STRATEGY MODELS

Market entry and growth strategy models include those on decisions such as the order and timing of entry, forecasting, and new-product introduction. Market entry strategy involves decisions on the following questions: which markets should a brand enter and what growth strategy should it follow? When should a brand enter a particular market or country (order and timing of entry) and with what introduction strategy and degree of innovativeness? What are the predicted or forecasted sales for a new brand? In the international context, which countries should a new product or brand enter? How (in what order and with what marketing support) does or should the brand enter multiple countries?

To primarily address the effects of order of entry and innovativeness on a brand's sales, Shankar, Carpenter, and Krishnamurthi (1998) develop a brand level repeat purchase diffusion model with competitor diffusion effects. Their model is both descriptive and predictive. It posits brand sales as the sum of brand trials and repeat purchases. The trials follow a generalized Bass model and are a function of innovative and noninnovative competitor cumulative sales and total marketing expenditures of the various brands.

They estimate the model using data on 13 brands from two ethical drug categories. Their results show that innovative late-entrant brands can surmount pioneering advantage by enjoying a higher market potential and a higher repeat rate than the pioneer or noninnovative late movers, growing faster than the pioneer, slowing the growth of the pioneer, and reducing the pioneer's marketing mix effectiveness. The model used by Shankar, Carpenter, and Krishnamurthi (1998) and the results thereof provide insights into the order and timing of market entry and its trade-offs with innovativeness.

While all the previously discussed models capture the effects of innovativeness, order and timing of entry, and marketing efforts on sales, they do not explicitly address the issue of a

brand's introduction strategy. Gatignon, Weitz, and Bansal (1990) specify a set of hypotheses about brand introduction strategies and identify the conditions under which a given marketing mix (excluding price) is more effective than another for continuous product innovations. They use a market share descriptive regression model in which brand market share is a linear function of relative product quality, detailing share, concentration ratio, number of brands (experience) in product category, and firm size. They also express detailing and the parameter associated with it as functions of exogenous variables such as market growth rate and market size. They estimate the model on cross-sectional data from 68 new drugs from 39 firms that were introduced during 1978–1982.

They find that the amount of communication efforts used to introduce a brand depends on the availability of financial resources. Their empirical analysis supports the importance of market growth and superior quality of the new product relative to existing products. It also shows that competitive structure of the market is extremely important, supporting the need for competitive analysis.

Their model and results were the first to shed light into an important phenomenon, but they did not analyze longitudinal data that are important in capturing the dynamic effects of launch strategies. They also do not capture the roles of order and stage of brand entry on sales into the launch strategy of a brand.

Shankar, Carpenter, and Krishnamurthi (1999) examine the effect of the stage of the product life cycle in which a brand enters on its sales through brand growth and market response, after controlling for the effects of order of entry and time in market. Their descriptive model of brand sales is a function of order of entry of the brand, time in market for the brand, cumulative sales of competitor brands, perceived product quality of the brand, and marketing mix expenditures of the brand and its competitors.

Estimating a dynamic brand sales model using 29 brands from six pharmaceutical markets, they report that the brand growth rate follows an inverted V pattern. They find that growth-stage entrants grow faster than pioneers and mature-stage entrants; competitor diffusion hurts the pioneer, has no effect on

growth-stage entrants, and helps mature-stage entrants; growth-stage entrants enjoy greater response to perceived product quality than pioneers and mature-stage entrants; pioneers enjoy higher advertising and sales force response than growth-stage entrants, which, in turn, have higher response than mature-stage entrants. They did not find a direct effect of order of entry or pioneering advantage.

These insights are useful for firms planning their entry and introduction strategies. Their data, however, did not include failed entries or exits from the market. Moreover, none of the previously discussed models consider the anticipated reactions of incumbents in deciding the launch strategy of a brand.

Shankar (1999) includes anticipated incumbent reactions in his model of the drivers of brand introduction strategy through an integrated framework that includes the determinants of both new-product introduction and incumbent response strategies. His joint model focuses on the interrelationship between new-product introduction and incumbent response strategies and on the role of multimarket contact in these strategies. Although the model is not normative, it has normative implications as it is based on rational expectations of firms. His new-product introduction model comprises both short-term and medium-term advertising and sales force expenditures of new brand as functions of the leadership of the brand in that marketing mix variable, size of the entrant, relative quality of the new brand, market experience of the entrant, anticipated reactions or marketing spending of large and small incumbent firms, multimarket contact of entering brand with incumbent firms, market size, and market growth rate. His incumbent reaction model consists of incumbent's ratio of spending in a marketing variable before and after the entry of the new brand, scale of entry of brand, brand dominance of incumbent at the time of entry of the new brand, and estimated elasticity of incumbent in the marketing variable after entry of the new brand.

He tested his model using US market data from several prescription drug categories. His findings show that new-product introduction strategy is influenced significantly by incumbent reaction strategy and vice versa. His results show that the relationship of a new product's

marketing spending to the anticipated incumbent reaction differs across incumbents by size-anticipated reactions from large incumbents lead to low-entrant spending while anticipated reactions from small incumbents do not pose a threat to a new brand's spending. He finds that greater market experience helps reduce uncertainty about the effectiveness of marketing variables and contributes to greater entrant spending. By incorporating anticipated incumbent reactions, Shankar (1999) offers a model of new brand introduction strategy and important results. All the studies discussed thus far do not address decisions involving multiple international markets or countries.

With regard to international market entry decisions, there are two major decision variables: scope (extent of exposure across markets) and speed (how fast) of entry, leading to two possible strategies, namely, sprinkler (fast rollout) and waterfall (steady rollout) strategies. An example of a model of market entry strategy across international markets is a descriptive model of relative market share with endogenous entry and marketing mix variables (Fischer, Shankar, and Clement, 2005). This model captures the moderating effects of international market scope and speed of rollout of late-mover brands on their market shares relative to the pioneer in the focal country or market. They estimate the model by accounting for the endogeneity of international market entry strategy, order of entry, resources, quality, and other decision variables, as well as for unobserved effects, using pharmaceutical data on 73 brands from two product categories in eight European markets during 1987–1996. Their results show that broader international market scope is associated with a lower late-entry penalty and a greater marketing spending efficacy for late-mover brands. They find that speed of rollout, however, is unrelated to late-entry penalty, but a waterfall rollout strategy is associated with a greater marketing spending efficacy. They argue that late-mover brands that sequentially enter many large international markets can challenge the market pioneer in a country more effectively than other late-mover brands.

Taken together, the models offer some useful insights for marketing strategy. A brand's decision to enter a new market or country is based not only on the sales potential for that brand in

that market but also on the overall sales potential across multiple markets or countries and the regulatory processes in the different markets. A market pioneer grows faster, and enjoys greater repeat purchase rates than me-too late movers. Innovative late entrants, however, can grow faster than the pioneer and slow the pioneer's growth and marketing spending effectiveness. For a late mover, a strategy of entering the largest markets sequentially (waterfall strategy) may potentially reduce its late-entry penalty. Robust sales forecasting models can predict both trials and repeat purchases of new brands in the presence of competitive effects.

There are some areas that need further research and models as well. First, we need more models of market exits. Second, models capturing the effects of synergy across the brands of a firm on their market entry decisions merit future investigation. Third, more research is required on repeat purchase and brand diffusion models. Fourth, as product life cycle curves are different for different product categories, we need more empirical models across different product categories and different time periods to study these differences. Finally, more models on market evolution for new products and brands across countries are needed.

DEFENSIVE STRATEGY MODELS

Models on defensive strategy comprise competitor reaction or incumbent response models. Competitor response to new-product entry plays an important role in determining the evolution of the market. Both normative and descriptive models have been developed for response to new-product entry. Several normative or game theoretic models of incumbent response have been developed.

Descriptive models of competitor response to new entry have used econometric analyses of data from several industries. Gatignon, Anderson, and Helsen (1989) address how established competitors in an oligopoly react to a new-product entry in their market. They estimate an econometric model of demand response functions and reaction functions with data from the airline and over-the-counter gynecological (OTC-Gyn) product markets. Their descriptive model comprises brand

market share as a function of advertising share and new market entries. They estimate the model with data from reactions to two new entries in an OTC-Gyn product market.

They argue that reaction time can be better understood and predicted by observing the effectiveness of a current competitor's marketing mix instruments. They find that incumbent firms react positively (retaliate) with their elastic marketing weapons and cut back (withdraw) with their inelastic marketing mix instruments. They assume that incumbent elasticities were not significantly altered by the new entrant.

Shankar (1997) develops a normative model of pioneer's defensive reaction and entrant's marketing mix spending. He develops a decoupled multiplicative sales response model in which a late-mover brand enters the market occupied by the pioneer and alters the pioneer's elasticity. The pioneer's sales response after the late mover's entry is specified as a function of advertising spending, sales force spending, price, and "time in market" of a new brand. By maximizing the profit function with respect to advertising, sales force spending, and price, he derives the equilibrium levels of spending for advertising and sales force. His result holds if both the pioneer and the late mover play a Nash game in all marketing instruments or if the late mover is a Stackelberg follower in one or all of the marketing instruments. He develops equilibrium reactions under Nash and different leader-follower games and empirically illustrates the analytical results with empirical analysis of data from a large pharmaceutical market.

On the basis of these results and the assumptions, he explains the pioneer's reactions and predicts its shift in marketing mix allocation upon new entry using empirical analysis of simultaneous and sequential games. He finds that the type of competitive game and the anticipated impact of the late mover on the pioneer's margin and elasticities are two critical factors that significantly affect the pioneer's decisions, in addition to the pioneer's characteristics and the market conditions considered by prior research. His results show that a follower (leader) role in a marketing mix variable, a static (growing) market, a decrease (increase) in own elasticity and margin generally lead to accommodation (retaliation) in that variable. He also highlights

cases in which general reactions do not hold and points out that it is necessary to look not only at one factor at a time but also examine the combination of all the factors. He argues that the shift in pioneer's equilibrium marketing mix allocation follows changes in its relative marketing mix effectiveness, which depends on the structure of competition, the impact of the late mover on its elasticities and margins, and the competitor's marketing mix.

Shankar's (1997) model and results offer interesting insights into incumbent reaction strategy. The defensive strategies proposed by his model are both theoretically and empirically driven, so they have important normative implications for managers. His empirical analysis, however, is based on one product category and his model does not include the role of multimarket contact in formulating the incumbent's defensive strategy.

Shankar's (1999) model, discussed earlier, incorporates the role of multimarket contact in incumbent's reactions. His results show that incumbent reaction is strongly related to new entrant spending. They show that incumbents react mildly to high entrant spending to avoid a competitive spending war and that multimarket contact between the incumbent and the entrant leads to milder incumbent response.

Collectively, these models offer some generalizable insights. When a new brand enters a market, incumbents retaliate with their competitively strong variables and accommodate with their competitively weak variables. An incumbent brand's defensive strategy is related to the entrant's new-product introduction strategy and vice versa. An incumbent tends to accommodate a new entrant when a new brand enters with a high level of spending and when they compete in multiple product markets.

There are many unexplored or underexplored issues relating to defensive marketing strategy models. First, models capturing the speed and duration of response will be useful for strategic decision making. Secondly, we need models of competitor reactions that capture multimarket competition across international markets. Thirdly, we require models to capture the reaction strategy of established brands when store brands or private labels are about to enter the market. Finally, we need more decision

support systems (Wierenga, van Bruggen, and Staelin, 1999).

CONCLUSION

Marketing strategy models continue to grow in importance. We have gained a good understanding of some of important marketing strategy issues, such as, new-product development, product management, market entry and growth, and defensive strategies, through carefully developed and tested, descriptive, normative, and predictive models. The models range from standard econometric models to high-level game theoretic models. The models developed thus far have provided some generalizable insights into strategic marketing decisions. We need more models for international entry, allocation between R&D and marketing expenditures, product portfolio analysis, allocation across own marketing initiatives and strategic alliances and across own and comarketing spending, and greater decision support systems.

marketing planning

Nigel F. Piercy

THE PROCESS OF MARKETING PLANNING

Marketing planning is the organizational process consisting of the managerial activities, systems, analytical techniques, and formal procedures aimed at producing marketing plans. Marketing planning is a critical element of marketing strategy formulation and implementation; for example, see McDonald (2007). Planning involves a thorough strategic MARKETING AUDIT of the firm's strengths and weakness in relation to the opportunities and threats in a chosen target market (see SWOT ANALYSIS).

When marketing strategy extends beyond a single year, executives may develop a three- or five-year strategic marketing plan, as well as an annual plan to manage marketing activities during the year. Budgets for marketing activities are normally set annually. Planning frequency varies by company, business unit, market, and marketing activity. Market targeting and positioning choices are not changed significantly during the year, while tactical changes in product, distribution, price, and promotion strategies may be included in the annual plan.

The responsibility for marketing planning normally rests with a marketing executive or team. Regardless of format, the marketing plan is developed in close coordination with the strategic plan for the business. Increasing emphasis is being placed on involving all business functions in the marketing planning process, because coordination with other functions (R&D, finance, and operations) is essential (Hulbert, Capon and Piercy, 2003).

THE PURPOSE AND SCOPE OF MARKETING PLANNING

The marketing plan indicates the marketing objectives and strategy (see MARKETING STRATEGY), as well as the tactics for achieving objectives. Importantly, the plan provides a framework for *strategy implementation* (see MARKETING STRATEGY IMPLEMENTATION) and for control of marketing strategies and programs. Marketing plans are developed,

implemented, evaluated and adjusted to keep the marketing strategy on target. Accordingly, marketing planning plays an integral role in the strategy process and is important to organizational learning capabilities (Piercy, 2009).

The plan represents the written statement of strategy and programs for each target market as a basis for actions. It may be the primary way for executives to obtain financial budget for a strategy, and to communicate the outcomes of strategy analysis to the organization.

In complex planning situations, the strategic business unit strategy indicates market target priorities, available resources, financial and other constraints, and other strategic guidelines required to develop marketing plans. The choice of planning unit will vary according to the company's product-market portfolio. Some firms plan and manage by individual products or brands, while others work with product lines, markets, or specific customers.

CONTENT OF A MARKETING PLAN

The format of marketing plans varies widely between organizations. Typically a marketing plan should specify the expected results (objectives), market targets, actions and responsibilities, schedules and dates, and control metrics. The plan should indicate details and deadlines, product plans, advertising and sales promotion actions, training requirements, and other information needed by line managers (for detail, see Cravens and Piercy, 2009).

Accordingly, an annual marketing plan should incorporate a *strategic situation summary* (describing markets, segments, competition and their strengths and weaknesses, and the company's competitive advantage in each segment of interest); *market target description* (defining and describing each market target and positioning strategy guidelines); *objectives for each market target* (objectives should be defined for each market target indicating financial performance, sales, market position, customer satisfaction, and other metrics); *marketing program positioning strategy* (how the firm wants to be positioned (see POSITIONING ANALYSIS AND STRATEGIES)) relative to the competition in the buyer's perspective, including statements of *product strategy* (setting the strategy for new products,

2 marketing planning

product improvements, and product deletions), *distribution strategy* (indicating the strategy for each distribution channel, including the role of channel members, assistance and support provided, and specific activities planned), *price strategy* (the role of price in the marketing strategy and actions planned) (see PRICING STRATEGY), and *promotion strategy* (indicating the planned strategy and actions for advertising, publicity, Internet, personal selling, and sales promotion); *marketing research* (information needs and planned projects); *coordination with other functions* (specifying responsibilities and activities of other departments that have an important influence on the planned marketing strategy); *performance metrics* (see MARKETING METRICS) (specifying the measures to be used to evaluate actual performance compared to the plan); and *forecasts and budgets* (predictions of revenues, profits, and costs to implement the marketing plan).

MANAGING THE MARKETING PLANNING PROCESS

Executives' perceptions of the usefulness of marketing planning vary from favorable, to seeing planning as a bureaucratic ritual. These perceptions reflect how well the planning process is managed, and the link to strategy implementation.

A process perspective on planning emphasizes the need to design and manage planning process consistently to combine an analytical perspective (tools and techniques of analysis) with the behavioral dimension of planning process (executive perceptions, attitudes, participation, and assumptions) and the organizational context for planning.

MARKETING PLANNING AND THE STRATEGY IMPLEMENTATION PROCESS

Marketing planning should be evaluated in terms of achieving the outcomes specified in the plan. Nonetheless, the result of marketing planning is determined largely by the effectiveness of the strategy implementation process (see MARKETING STRATEGY IMPLEMENTATION). A good implementation process linked to marketing planning spells out the activities to be implemented, who is responsible for implementation, the time and location of implementation, and how implementation will be achieved. Two sets of factors are influential in determining implementation effectiveness: structural issues (including the company's marketing functions, control systems, and policy guidelines) and behavioral issues (concerning marketing executives' skills in bargaining and negotiation, resource allocation, and informal organizational networks) (Noble and Mokwa, 1999).

marketing strategy

Rajan Varadarajan

INTRODUCTION

Strategy exists at multiple levels in an organization, chief among them being strategy at the corporate, business unit, and functional levels such as marketing and R&D. Although the focus of this article is on marketing strategy, in light of the interdependencies between strategies at different levels in an organization, a brief overview of strategy at the corporate and business unit levels is presented first. This is followed by an in-depth discussion on marketing strategy focusing on the following issues: (i) perspectives on marketing strategy and the scope of marketing strategy; (ii) definition of marketing strategy; (iii) marketing strategy content and formulation process; and (iv) marketing strategy drivers and outcomes.

Corporate strategy refers to a firm's choice of businesses to be in. While some firms choose to remain as *single-business* firms, the prototypical, large firm of the twenty-first century in most regions of the world is a *multibusiness* firm. At the corporate level, a multibusiness firm's decisions regarding the choice of businesses to be in and the allocation of resources among businesses in its portfolio entail focusing on issues such as

- addition of new businesses to the firm's portfolio (diversification strategy);
- deletion of businesses from a firm's portfolio (divestitures strategy);
- mode of entry into new businesses (acquisition, internal development, joint venture, merger);
- mode of exit (sell-off, spin off);
- effective management of businesses retained (mission assignment and resource allocation among businesses in a firm's portfolio).

Business strategy refers to how a particular business in a firm's portfolio chooses to compete in the marketplace. The terms *business strategy*, *business unit strategy*, *competitive strategy*, *competitive business strategy*, and *market strategy* are used interchangeably in literature to refer to the

strategy of a specific business unit in the portfolio of a multibusiness firm. The fundamental issue here is viewed as the manner in which the business achieves and sustains a competitive advantage (Teece, Pisano, and Shuen, 1997). A business achieves a competitive advantage by leveraging the distinctive skills and resources of the firm to implement a value-creating strategy that its competitors cannot implement as effectively (Barney, 1991). The skills and resources that a business can leverage to achieve a competitive advantage encompass those of the firm at large and are not limited to those that normally reside within the business (*see COMPETITIVE ADVANTAGE: ITS SOURCES AND THE SEARCH FOR VALUE*). Competitive advantage that is immune to erosion by competitive actions results in a sustainable competitive advantage. Viewed from the perspective of organizational functions, business strategy is multifunctional in scope.

Porter (1980, 1985) distinguishes between four broad generic strategies that entail different routes to achieving a sustainable competitive advantage as a basis for long-run, above-average performance:

- *Cost leadership*: achieving a competitive advantage through lower cost in a broad range of industry segments.
- *Differentiation*: achieving a competitive advantage through differentiation in a broad range of industry segments.
- *Focused cost leadership*: achieving a competitive advantage through lower cost in a narrow industry segment.
- *Focused differentiation*: achieving a competitive advantage through differentiation in a narrow industry segment.

Cost leadership strategy entails a business leveraging the distinctive skills and resources of the firm to achieve a defensible position of competitive cost advantage in the marketplace (i.e., being the lowest cost producer). *Differentiation strategy* entails a business leveraging the distinctive skills and resources of the firm to differentiate its product offerings from those of its competitors to achieve a defensible position of competitive differentiation advantage in the marketplace. Pursuing a cost leadership strategy does not necessarily mean selling the product at the lowest

2 marketing strategy

price relative to competitors, but possessing the ability to compete on price, if warranted. In other words, cost leadership implies the inability of a business' rivals to compete on the basis of price in order to attract customers. However, this does not preclude a rival multibusiness firm that is able to achieve a competitive cost advantage from economies of scope from being able to compete on the basis of price. A differentiation strategy manifests as attributes or features in a business' product offerings that appeal to customers at large or to specific customer groups and for which they are willing to pay a higher price. In effect, the nonprice attributes of the business' product offering become more salient to buyers from the standpoint of brand choice decision. The effectiveness of a differentiation strategy is further enhanced when the market is segmented into homogeneous groups and distinctive value propositions are offered to each group (i.e., heterogeneity in customers' preferences is adequately met) (see MARKET SEGMENTATION AND TARGETING; POSITIONING ANALYSIS AND STRATEGIES; A FRAMEWORK FOR CREATING VALUE PROPOSITIONS).

There is considerable overlap in the domains of business strategy and marketing strategy, as conceptualized in management (strategic management) and marketing (strategic marketing) literature, respectively. Regardless, corporate, business, and marketing strategy interact together to shape the competitive positional (cost and/or differentiation) advantages of individual businesses in a firm's portfolio. Varadarajan and Clark (1994) provide an overview of the distinctive and overlapping domains of (i) corporate strategy and business strategy, (ii) corporate strategy and marketing strategy, (iii) business strategy and marketing strategy, and (iv) corporate strategy, business strategy, and marketing strategy. Varadarajan, Jayachandran, and White (2001) provide an overview of how a business' marketing strategy is influenced by and influences the firm's corporate strategy.

PERSPECTIVES ON MARKETING STRATEGY AND THE SCOPE OF MARKETING STRATEGY

Broad to narrow: from comprehensive vector of decisions to a specific element of the vector. Mar-

keting strategy, as an *umbrella* term, encompasses a number of strategy concepts, spanning from broad and comprehensive to narrow and focused marketing behaviors directed at consumers, customers, competitors, and/or other key constituencies in the marketplace. For example, the term *marketing strategy* is used in both marketing literature and marketing practice to refer to

- a comprehensive vector of marketing decisions encompassing numerous aspects of where to compete (e.g., markets to serve and market segments to target) and how to compete (e.g., multifaceted differentiation);
- a vector of marketing decisions encompassing numerous aspects of how to compete;
- a vector of marketing decisions concerning certain aspects of how to compete (e.g., push strategy versus pull strategy – pattern of allocation of resources among the advertising, personal selling, consumer sales promotion, and trade sales promotion elements of the promotion mix); and
- a marketing decision concerning a specific aspect of how to compete (e.g. market skimming price strategy versus market penetration price strategy, positioning strategy, and branding strategy).

Broad versus narrow: construal of marketing strategy as a single all-encompassing continuum versus one of two underlying continua. Defining marketing strategy necessitates addressing the question of the distinction between *marketing strategy* and *marketing tactics*. An examination of journal articles and marketing textbooks (textbooks on principles of marketing, marketing management, and marketing strategy) reveals diverse points of view regarding the purported distinction between marketing strategy and marketing tactics including the following: (i) the marketing behaviors of firms in the realm of the 4Ps (product, promotion, price, and place/distribution) are characterized as marketing strategy in some sources and as marketing tactics in other sources; in sources in the latter category, marketing behaviors pertaining to segmentation, target market

selection, and positioning (STP) are considered as the domain of marketing strategy and behaviors pertaining to the 4Ps as the domain of marketing tactics; (ii) in yet other sources, some elements of the 4Ps are characterized as pertaining to marketing strategy (product and place/distribution) and others as pertaining to marketing tactics (price and promotion); and (iii) in still other sources, certain marketing behaviors in the realm of each of the 4Ps are characterized as marketing strategy (e.g., promotion – push versus pull strategy; price – market skimming price strategy versus market penetration price strategy) and others as marketing tactics (e.g., promotion tactics and pricing tactics). Viewed against the backdrop of the dictionary *definition of definition* (an explanation or statement of the essential nature of anything), defining marketing strategy in terms of specific marketing behaviors that fall within its scope (e.g., STP-related behaviors of organizations) and those that fall outside of its scope (e.g., product, promotion, price, and place-related behavior of organizations) is problematic.

In the context of military and warfare, the concepts of strategy and tactics have an illustrious history. However, the adaptation of these concepts into some of the business disciplines including marketing has been haphazard and arbitrary. In reference to the delineation of the behavior of firms as strategic and tactical behaviors, Mintzberg 1987, p. 14) notes “*The point is that these sorts of distinctions can be arbitrary and misleading, that labels should not be used to imply that some issues are inevitably more important than others. . . . Thus there is good reason to drop the word “tactics” altogether and simply refer to issues as more or less “strategic,” in other words, more or less “important” in some context, whether as intended before acting or as realized after it.*”

The definition of marketing strategy presented here is based on the construal of the broad array of marketing behaviors of organizations as a *single underlying strategic continuum* rather than two distinct continua – strategic and tactical behaviors. All else being equal, it can be expected that the *resource commitments* associated with the marketing behaviors of organizations that are more strategic are (i) made with a relatively greater focus on facilitating

the achievement of competitive advantage; (ii) relatively larger in magnitude; (iii) made with a relatively longer term orientation; (iv) made over a relatively longer time period, (v) relatively more difficult to reverse; and (vi) relatively more interdependent and internally consistent.

Broad and broadening: marketing strategy in an Internet-enabled market environment. Marketing strategy is generally viewed as principally concerned with an organization’s decisions pertaining to where to compete and how to compete. Realistically, organizations in their own self-interest are likely to constantly explore and experiment with new ways of competing in the marketplace. Furthermore, developments in the macroenvironment often present organizations with new ways of competing in the marketplace, and thereby broaden the scope of marketing strategy (i.e., the vector of marketing decisions pertaining to how to compete in the marketplace). A case in point is the broadened scope of marketing strategy in the aftermath of the evolution of the competitive landscape from a predominantly physical marketplace to a marketplace encompassing both the physical and the electronic marketplaces (i.e., the Internet-enabled market environment), that is, a consequence of the competitive imperative to leverage the potential of the Internet to more effectively compete in the marketplace is the broadening of the scope of marketing strategy (see DIRECT AND INTERACTIVE MARKETING; E-COMMERCE AND INTERNET MARKETING). The change in the frame of reference for competitive marketing strategy from “How to compete in the physical marketplace?” to “How to compete in an Internet-enabled market environment that encompasses both the physical marketplace and the electronic marketplace?” has effectively broadened the vector of marketing decisions encompassing issues such as the following:

1. What should be the relative emphasis on traditional channels versus the electronic channel (i.e., the Internet) for
 - providing product-related *information* to customers;
 - *communicating* with customers;
 - *promoting* to customers;

4 marketing strategy

- *transacting* with customers;
 - *distributing* information products in digital form; and
 - *customer trial/sampling* facilitation of information products in digital form.
2. What should be the relative emphasis on
 - marketing direct to customers via the Internet versus through intermediaries (traditional, electronic, and/or hybrid intermediaries) (see MULTICHANNEL MARKETING; DISINTERMEDIATION);
 - market pioneering (order of entry strategy); and
 - strategic alliances.
 3. How can the potential of the Internet be leveraged to enhance innovations, customization, and augmentation in the product, price, promotion, and distribution elements of the marketing mix?
 4. How can the potential of the Internet be leveraged to market an organization's offerings to new market segments and in new geographic markets?
 5. How can the potential of the Internet be leveraged to market an organization's offerings in fundamentally new ways (new business models) (see Varadarajan and Yadav, 2002 for additional insights)?

Understandably, characterization of the prevailing market environment as an Internet-enabled market environment would be appropriate only in the context of markets in certain countries. Hence, the scope of marketing strategy (the breadth of the vector of competitive tools available to organizations to compete in the marketplace) is context dependent. Against this backdrop, a broad definition of marketing strategy and two somewhat focused definitions of marketing strategy are presented in the next section.

DEFINITION OF MARKETING STRATEGY

The creation, communication, and delivery of products that offer value to customers in an exchange are central to various definitions of marketing. For instance, the American Marketing Association's (AMA) official definition of marketing reads as follows: "Marketing is the activity, set of institutions, and processes

for creating, communicating, delivering, and exchanging offerings that have value for customers, clients, partners, and society at large (Marketing News, 2008, p. 28)." The creation, communication and delivery of products that offer value to customers in an exchange are also central to the definition of marketing strategy. At the most fundamental level, marketing strategy pertains to an organization's *decisions* that specify its *choice* of actions (from among alternatives) for creating, communicating, and delivering products that offer value to customers in an exchange.

At the broadest level, marketing strategy can be defined as an organization's integrated pattern of decisions that specifies its crucial choices concerning products, markets, marketing actions and marketing resources in the creation, communication and/or delivery of products that offer value to customers in exchanges with the organization and thereby enable the organization to achieve specific objectives. With reference to a specific product offering of an organization, the above definition can be stated somewhat succinctly as follows: *Marketing strategy refers to an organization's integrated pattern of decisions that specify its crucial choices concerning markets to serve and market segments to target, marketing actions to take, and the allocation of marketing resources among markets, market segments, and marketing actions toward the creation, communication, and/or delivery of a product that offers value to customers in exchanges with the organization and thereby enable the organization to achieve specific objectives* (see Varadarajan, 2010).

While organizations are faced with the need to address issues relating to "how to compete" on an ongoing basis and make midcourse changes as appropriate, the question of "where to compete" (choice markets to serve and market segments to target) is an issue that is addressed relatively infrequently. Hence, with specific reference to an existing product offering of an organization that is targeted at specific markets and market segments, the proposed definition can be stated even more succinctly as follows: *Marketing strategy refers to an organization's integrated pattern of decisions that specify its crucial choices concerning marketing actions to take, and the allocation of marketing resources among markets, market segments, and marketing actions toward*

the creation, communication, and/or delivery of a product that offers value to customers in exchanges with the organization and thereby enable the organization to achieve specific objectives (see Varadarajan, 2010).

The use of the terms *decisions* and *actions* in the definitions of marketing strategy merit brief elaboration. Within reason, the terms *actions*, *activities*, and *behaviors* can be used interchangeably. An organization's implementation of its marketing strategy *decisions* manifest as its marketing *actions* or marketing *activities* or marketing *behaviors* in the *marketplace*. Although a number of marketing *activities* also occur within the boundaries of an organization (e.g., new product development related activities; sales force training related activities), it is an organization's actions, activities, or behaviors in the marketplace directed at entities external to the organization such as its consumers, customers, and competitors that define its marketing strategy. In other words, it is to an organization's marketing actions, activities or behaviors in the marketplace that customers respond and competitors react (see Varadarajan, 2010 for a detailed discussion on the literature underpinnings of the above definitions and elaboration of the various constituent elements of the definitions).

MARKETING STRATEGY: CONTENT AND FORMULATION PROCESS AND DRIVERS AND OUTCOMES

Chief among the marketing strategy related questions of enduring interest to marketing educators and practitioners are the following:

1. What is marketing strategy (i.e., the *content* of marketing strategy, the primary focus of this article)?
2. What *processes* do organizations employ in order to make decisions concerning marketing strategy content (i.e., the marketing strategy formulation *process*) (see COMPETITIVE ADVANTAGE: ITS SOURCES AND THE SEARCH FOR VALUE; COMPETITIVE ANALYSIS; COMPETITOR ANALYSIS; MARKETING STRATEGY MODELS; MARKETING PLANNING; POSITIONING ANALYSIS AND STRATEGIES)?
3. What are the principal organizational and environmental *drivers* or *determinants* of an organization's marketing strategy (see MARKET ORIENTATION; MARKET/INDUSTRY STRUCTURE; SWOT ANALYSIS)?
4. What are some of the *outcomes* of marketing strategy that are of principal concern to organizations (see PERCEPTION OF BRAND EQUITY; CUSTOMER EQUITY; BRAND VALUE; MARKET-BASED ASSETS)?

Table 1 provides additional insights into marketing strategy content and process-related issues as well as drivers and outcomes of marketing strategy. Specifically, the table highlights the focus of some of the other articles in this encyclopedia that relate to (i) marketing strategy content; (ii) marketing strategy formulation process; (iii) drivers of marketing strategy; and (iv) outcomes of marketing strategy.

Figure 1 presents a conceptual framework delineating the drivers and outcomes of marketing strategy (see Varadarajan and Yadav, 2002 (p. 298 to 309) for additional insights into the literature underpinnings of the links shown in Figure 1). As shown in the figure, chief among the factors influencing a business' competitive marketing strategy are the following:

1. distinctive skills and resources possessed by the firm (as noted earlier, the large, prototypical twenty-first century firm in most regions of the world is a multibusiness firm; hence, the term *firm* is used to refer to multibusiness firms and the term *focal business* or *business* is used to refer to a specific business in the portfolio of a multibusiness firm; in the case of single-business firms, the terms *firm* and *business* refer to the same entity);
2. structural characteristics of the market/industry in which the focal business competes;
3. characteristics of the focal business' product offerings;

^aBrand equity as a firm resource is a driver of marketing strategy (a resource that is leveraged to compete in the marketplace). Creating market-based assets such as brand equity, customer equity, and channel equity is an important objective of marketing strategy (i.e., an outcome in Figure 1). Leveraging the equity of a brand name in a firm's brand portfolio to enter a new product category relates to marketing strategy content. Similar reasoning is the basis for listing some of the other topics under multiple categories in the table 1.

^b*Content*: Willingness to cannibalize as a deliberate strategy. *Outcome*: The financial and marketplace performance consequences of product cannibalization.

^cCustomer life time value is both a driver (*buyer characteristic*) and outcome (*marketplace and financial performance*) of marketing strategy.

^d*Content*: First to market as a deliberate strategy. *Outcome*: Competitive positional advantages of market pioneering. Although competitive advantage is not shown explicitly in Figure 1 as an outcome of marketing strategy, chief among the objectives of marketing strategy is the facilitation of the achievement of competitive positional advantage (cost and/or differentiation advantage).

^e*Content*: Early follower or late entry as a deliberate strategy. *Outcome*: Competitive positional advantages of later entry.

^f*Process and Content*: Consider for instance Kohli and Jaworski's (1990, p.6) definition of market orientation: "Market orientation is the generation of organization-wide market *intelligence* pertaining to current and future customer needs, *dissemination* of the intelligence across departments and organization-wide *responsiveness* to it." The definition spans both process (intelligence generation and dissemination) and content (responsiveness). See Han, Kim and Srivastava (1998) for insights into the role of market orientation on the innovation strategy of firms.

8 marketing strategy

4. characteristics of the buyers of the focal business' product offerings; and
5. macroenvironmental factors – economic, political and regulatory, social, technological, and so on – and changes in the macroenvironment (e.g., the impact of a technological development such as the Internet on how businesses compete in the marketplace).

The outcomes of marketing strategy are broadly delineated in Figure 1 as marketplace performance outcomes (e.g., market share, market share rank, customer satisfaction, customer loyalty) and financial performance (e.g., return on investment, customer lifetime value). Although not shown in the figure, it should be noted that marketplace and financial performance outcomes are also drivers of marketing strategy. Specifically, the impact of the marketplace performance and financial performance during time period, t , and earlier

time periods on marketing strategy during time period, $t + 1$ are not shown in the figure. Also, in the interests of simplicity of exposition, mediated links between drivers of marketing strategy are not shown in the figure. Consider for instance, the following mediated link: macroenvironment characteristics → product characteristics → marketing strategy. The evolution of the market environment into an Internet-enabled market environment has had a major impact on the marketing strategy of producers of information products such as books, magazines, music, movies, newspapers, photographs, software, and videogames. Organizations extensively use the Internet as a distribution channel for information products in digital form as well as to facilitate product trial by consumers.

A business' marketing strategy decisions are influenced by both supply-side and demand-side considerations. In Figure 1, the links from firm characteristics, industry characteristics, and

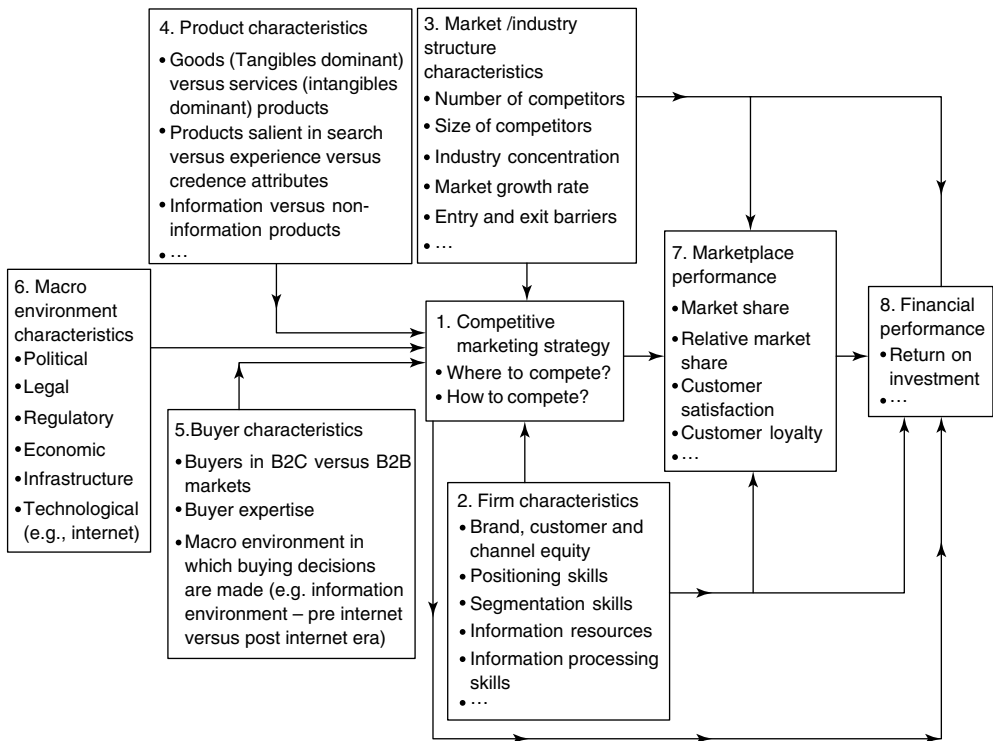

Figure 1 Marketing strategy: drivers and outcomes. (adapted from Varadarajan and Yadav (2002)).

product characteristics denote *supply-side drivers* of marketing strategy, and the link from buyer characteristics to marketing strategy denotes *demand-side drivers* of marketing strategy. The *structural characteristics of the industry* in which a business competes, a supply-side driver, refers to factors such as the number of competitors, size of competitors, entry and exit barriers, industry growth rate, and competitors' history of past behavior (see MARKET/INDUSTRY STRUCTURE). The *characteristics of a business' target customers*, a demand-side driver, refers to factors such as the attitudes, beliefs, and preferences, number and size, purchase frequency, sensitivity and responsiveness to various marketing instruments, and history of past behavior (see CUSTOMER ANALYSIS).

Of the supply-side and demand drivers shown in Figure 1, while the marketing strategy implications of firm characteristics is idiosyncratic to individual businesses competing in an industry (i.e., the marketing strategy implications of the heterogeneous resource endowments of competing businesses), the marketing strategy implications of the other three drivers are the same for all competing businesses. Consider, for instance, the growing importance of developing and nurturing two firm-specific skills and resources in the aftermath of the evolution of the market into an Internet-enabled market environment:

- *Information resources*: the nature and amount of information acquired and accumulated by the organization about individual customers.
- *Information technology resources and information processing skills*: the ability of the organization to use information technology (IT) resources and information processing skills to gain insights about individual customers and use this knowledge to customize its future interactions with these customers.

In an Internet-enabled market environment, an organization's information resources, information technology resources, and information processing skills are key *strategy enablers* in that they determine its ability (or lack thereof) to pursue certain marketing strategies as well as make more informed decisions in the realm of various marketing-mix variables. For instance,

an organization's ability to engage in *suggestive selling* (recommend products to an individual customer based on perceived similarity with the purchase patterns of other customers) depends on its information resources, IT resources, and information processing skills. Similarly, in the area of pricing, an organization's resources and skills in the above areas determine the extent to which it would be able to engage in more fine-tuned *price discrimination* (e.g., inferring buyers' price sensitivity from their web navigation and purchase behavior and offering products at prices customized to the level of individual buyers). An organization's information resources, IT resources, and information processing skills are also a critical determinant of its ability to pursue other strategies in the realm of pricing such as *dynamic pricing* (e.g., changing the price at which a product is offered on the basis of prevailing supply and demand conditions) (see Varadarajan and Yadav, 2002 for additional insights) (see DATABASE MINING AND MARKETING).

CONCLUSION

Marketing strategy refers to the *behavior* of an organization in the marketplace. Broadly construed, such behavior is *multifaceted* (e.g., positioning, differentiation, pricing, advertising, and distribution related behaviors), *coordinated*, *integrated*, and *internally consistent across multiple facets and directed at entities external to the firm* (e.g., end-use customers, intermediate customers, consumers, and competitors) with a clearly defined *purpose* (i.e., to achieve specific organizational objectives). The bases for an organization's behavior in the marketplace are its *decisions* pertaining to *where to compete* and *how to compete*. The implementation of an organization's marketing strategy *decisions* manifest as its marketing *actions, activities, or behaviors* in the marketplace.

market-based assets

Tasadduq Shervani

Market-based assets arise from the commingling of the firm with entities in its external environment. Brands, customer relationships, distribution channel, and other partner relationships are all examples of market-based assets (Srivastava, Shervani, and Fahey, 1998). Each such asset requires a focal firm, an entity from its external environment, and a relationship between the two that creates value for the focal firm.

Market-based assets are becoming more critical for firms as their value has become more dependent in the last 50 years on intangible assets, or assets that are not captured on the balance sheet of a firm. In fact, for many firms, market value is a multiple of their book value. It is critical for such firms to understand and explain the gap between their market value and book value. Although there are other types of intangible assets that can account for the gap between market and book value (e.g., intellectual assets such as patents), market-based assets play an important role in explaining this gap. In contrast to intellectual assets, market-based assets are relational assets that exist because of key relationships between a firm and its customers and partners.

These relational assets create value for a firm because they allow a firm to (i) accelerate cash flow, (ii) enhance cash flow, (iii) reduce the volatility and vulnerability of cash flows, and (iv) increase the residual value of cash flows. For example, brands can lead to faster trial and adoption of new products introduced by a firm, thus accelerating cash flows. Strong customer relationships can increase customer loyalty and retention, which can reduce the vulnerability of cash flows. A well-established and well-nurtured customer base is a socially complex, difficult-to-imitate, and relatively rare asset that can increase the long-term residual value of a firm.

The ultimate goal of the marketing function within a firm can be conceptualized as increasing the value of the market-based assets of the firm. Therefore, marketers must first assess the current value of their firm's market-based assets. The next step is to leverage market-based assets to create shareholder value by accelerating, enhancing, protecting and stabilizing cash flows. Finally, the effect of marketing actions to leverage such assets must be measured. This, in turn, will give marketers permission to invest in the next round of marketing programs and activities to strengthen their market-based assets and increase shareholder value.

Market-based assets have existed for as long as business has existed. However, the tendency in the past was to lump them together with all other intangible assets under the category of "goodwill." Goodwill was seen as a reward for having run a business successfully in the past. By understanding that market-based assets are a significant portion of the goodwill earned by a firm over time and by understanding the factors that lead to the development and exploitation of market-based assets, marketing researchers and practitioners can better understand how marketing creates value.

The relationship between marketing and finance, the two critical functions in any business, can be better managed using the common language of market-based assets. Finance personnel can now understand the value created by marketing in a language that they are familiar with. Marketers, in turn, can use this common language to ensure that the firm makes an appropriate investment in the marketing function and marketing activities.

mass customization strategies

Arun Sharma

The concept of mass customization is becoming increasingly important to businesses. To illustrate, on May 20, 2009, Amazon.com listed 46 books with the name mass customization in their title and 3000 books with mass customization as key words. Google Scholar listed more than 2000 articles and books with mass customization in their title. Mass customization is the strategy by which firms provide customers with products that are individually tailored to their specific needs. Mass customization strategies are extensively used in two domains, manufacturing and marketing. In manufacturing, the strategy refers to production techniques that allow firms to customize products at efficiencies of mass production. In marketing, mass customization is the strategy used in the practice of customer-centric marketing. Sheth, Sisodia and Sharma (2000) stated that in customer-centric marketing, marketers first assess each customer or potential customer individually and determine whether it is more profitable to serve that customer directly or through a third party. On the basis of that determination, customer-centric marketers then decide whether to create a customized or standardized product offering and/or some other element(s) of the marketing mix.

Mass customization requires modular and rapid assembly processes and therefore the shift from mass manufacturing to mass customization requires redesigning products and production processes. Consumers are generally aware that major firms such as Dell, Nike ID, and Land's End practice mass customization. Other firms that are less commonly known to practice mass customization include McDonald's and Chinese restaurants. Chinese restaurants are a classic example of mass customization strategies; a limited number of ingredients allow a Chinese restaurant to create an unlimited number of meal variations in a very rapid time frame.

Mass customization marketing strategies emerge when firms change from a supply-side orientation to a demand-side orientation. Mass customization marketing strategies also emerge

when customers' need for customization is high and matches marketers' ability to modularize production (Figure 1). In cases where marketers can customize but customers have minimal customization needs or desires, segmentation marketing strategies emerge (e.g., shampoo and detergent markets). When customers need or desire customization but marketers do not have the ability to modularize, component customization marketing strategies emerge. Examples of these marketing strategies are found in the clothing (alterations are done at the store) and automotive (dealer-installed accessories) industries. Finally, when marketers' ability to customize is low and customers do not need or want customization, mass marketing strategies dominate.

Even within mass customization, different marketing strategies emerge (Figure 2), based on whether customization is driven by a marketer or by customers. If the extent of customization is high by both a marketer and its customers, a "cocreation" marketing strategy often emerges. In cocreation, a marketer and its customers jointly develop a product offering. Cocreation marketing strategies have traditionally been limited to business-to-business marketing, but recently cocreation marketing strategies have been applied in consumer markets such as computers and automobiles. When customers drive customization and marketers do not, customizable products emerge. Examples of these types of products are software (customized by users) and cellular phones (customized ring tones, etc.). In the case of high marketer-driven customization and minimal customer-driven customization, these marketing strategies are characterized by environmentally driven products. Examples are gasoline (temperature-based additives), food (customized to region), and clothing (regional fashions).

In summary, mass customization is a strategy that enables the practice of customer-centric marketing. To successfully apply a mass customization strategy, marketers need to shift from a supply-side orientation to a demand-side orientation and change their product development and manufacturing processes.

marketing. *Journal of the Academy of Marketing Science*, 28 (1), 55–66.

multichannel marketing

Adel I. El-Ansary

Multichannel marketing is marketing through multiple channels to reach target market segments. Marketing channels may be classified in terms of formats initiated by manufacturers, wholesalers, retailers; or for that matter other channel members who perform marketing functions, participate in marketing flows, or facilitate marketing transactions. Retail-based channel formats are of particular interest to marketers because of their constant and direct connection to end user customers in general and consumers in particular. Retail formats consists of store retailing and nonstore retailing such as web sites (*see* MARKETING FUNCTIONS ON THE INTERNET), mail order catalogs, direct mail, and newer forms of technology such as text messaging and email. Traditionally, marketers refrained from the use of secondary channels, in order to avoid explicit conflict with primary channel members and implicit confusion in projecting brand image to their customers. Today, the emergence and continued growth of “multichannel customers,” led marketers to view multichannel marketing as the norm, rather than the exception (Coughlan *et al.*, 2006). When customers use different channels to search for information, compare brands and prices, and conclude related transactions, marketers find themselves compelled to use any combination of channels necessary to effectively communicate with their customers and render the purchase process more efficient.

Multichannel marketing is a powerful tool for businesses. Channels can interact and reinforce each other, ultimately giving marketers greater opportunities to network with existing and potential customer bases. Fostering business-customer interaction (*see* CONSUMER INVOLVEMENT) is one of the main purposes of multichannel marketing. Such interaction allows for greater promotion of products and services, leading to increased profits for the company, greater customer loyalty, reduced costs, and enhanced branding (*see* BRAND EXTENSIONS AND FLANKER BRANDS). Multichannel marketing also enables marketers to track customer behavior, thus creating a better

understanding of the customers’ *decision* (*see* CONSUMER DECISION MAKING) processes. By understanding the decision process, businesses can improve customer retention rates (Rangaswamy and VanBruggen, 2005).

There are two facets of multichannel marketing: the supply side and the demand side. Suppliers find multichannel marketing attractive because of increased market penetration (*see* SUPPLY CHAIN MANAGEMENT STRATEGY) and the potential to reduce competition through barriers to entry. Suppliers have access to various markets and segments thereof through multiple channels. The end consumer also gains from multichannel marketing. Multiple channels empower consumers to select channels that meet their demand (*see* INTEGRATED MARKETING COMMUNICATION STRATEGY) for service level outputs such as assortment, lot size, and delivery time. Also, by pitting channels against each other, consumers are able to demand more services at lower prices. Perhaps, the greatest contribution of multiple channel marketing is the ease of discovery. Suppliers and customers alike are able to locate each other with ease, and meet each other’s demands effectively (Coughlan *et al.*, 2006).

There are many factors that a marketing manager must consider when determining the appropriate channels to reach customers. Managers must determine who the potential customers are (*see* CONSUMER CATEGORIZATION), what products are those customers purchasing, when are they purchasing products, where are they buying products, and how are the products being purchased. Multichannel marketing is viewed differently by diverse firms. Some firms consider multichannel marketing as a means of diverting lower-valued customers to low-cost channels, such as web sites, in order to keep transaction costs down. However, other firms view multichannel marketing as means of reaching higher-valued customers (*see* SOCIAL CLASS).

There are challenges that arise when a firm decides to implement multichannel marketing. Aside from the potential of conflict, intrabrand competition and channel *cannibalization* (*see* CANNIBALISM) are problems that result in lost sales to competitors. Moreover, inconsistent *customer experience* (*see* THINKING DEEPER ABOUT CUSTOMER EXPERIENCE)

with various channels can negatively impact overall brand image (Eisenberg, 2009).

disintermediation

Rajendra Sisodia

Disintermediation refers to the removal of existing intermediaries from a supply chain (see SUPPLY CHAIN MANAGEMENT STRATEGY). Some refer to disintermediation simply as “cutting out the middleman.” The World Wide Web has made it cost effective for many companies to deal with more customers directly and has contributed to the trend toward disintermediation.

Traditionally, marketing has depended heavily on the presence of multiple intermediaries between a producer and consumer. These intermediaries add time and place utility to the functional utility “engineered” into the product or service offering of a producer. In addition to serving as physical conduits for getting products to the market, intermediaries also serve as informational conduits, conveying relevant information from producers to customers and customers to producers.

The advent of the World Wide Web changed the role of intermediaries in many industries. The Web enabled a high degree of market transparency, leading customers in some industries to initiate the process of disintermediation in search of lower prices. Simultaneously, a company’s virtual presence on the Web enabled a high level of accessibility almost immediately, and also enabled two-way information flow directly with end-users (customers). Companies could serve huge numbers of customers efficiently and effectively by automating many administrative tasks by means of the Web. This led to rapid growth in support services, such as customer relationship management.

A well-known example of *downstream* disintermediation is Dell, Inc., which achieved dramatic growth in the 1990s by selling direct to consumers and businesses. Wal-Mart has been successful at *upstream* disintermediation; by dealing directly with producers, it lowered its product costs and passed the savings along to customers.

Despite these well-known examples, the extent of Web-driven disintermediation has been less than was initially expected. This is because customers continue to value many of the

functions provided by retailers and wholesalers (such as credit, the ability to experience products, a wide assortment of offerings, and returns processing). Companies have also found that it is often less efficient to ship individual orders than shipping products in bulk to stores. Many retailers have also sought to enhance their own value to customers by integrating their physical and virtual presence (referred to as *bricks and clicks*). This has endeared them to customers who like being able to buy online and pick up or return products at a physical store, or vice versa.

REINTERMEDIATION

Reintermediation refers to the emergence of new types of intermediaries between end-users and producers after disintermediation has already occurred. New categories of intermediaries arise to capture value-creating opportunities through direct interactions between customers and producers. As with traditional intermediaries, these new types of intermediaries thrive based on the “economic transfer” principle: those that deliver greater value at lower cost tend to prosper.

For example, Priceline has emerged as a new type of market intermediary, using a “reverse auction” method to bring buyers and sellers together. The company refers to its patented business model as *buyer-driven commerce*. Potential buyers submit bids known as *conditional purchase offers* to buy products such as airline tickets at a certain price; sellers can either accept the offer, reject the offer, or counteroffer. Other examples of new types of intermediaries include rating services, automated ordering services, and services based on consolidating numerous small orders from many customers into more economically viable quantities.

In summary, the phenomena of disintermediation and reintermediation have both been driven by the dynamic and growing capabilities of the World Wide Web. The default position used to be that companies utilized intermediaries to create time and place utility, although there were conditions under which they could bypass middlemen and serve customers directly. The default position now appears to be that companies look first at going direct, although

2 disintermediation

many conditions exist under which it is beneficial to utilize specialized intermediaries.

point of difference and product differentiation

Rajendra Sisodia

In marketing, product differentiation refers to the process of taking what could otherwise be a commodity or homogeneous product and incorporating one or more useful and relevant points of difference into the overall product offering so that it offers more value to customers in an identified market segment. Product differentiation is one of the central concepts in marketing. The term was coined in 1933 by the American economist Edward Hastings Chamberlin, who also developed the theory of monopolistic competition. The objective of product differentiation is to create what advertisers term “a unique selling proposition.”

For somebody with a marketing mind-set, there is no such thing as a commodity. Every product or service can be differentiated. This includes products intended for businesses as well as for consumers. Products need to be differentiated from those of competitors, as well as from a company's other products.

When products are differentiated, the offerings of different companies are no longer perfect substitutes, and customers cannot readily compare them with one another. This reduces the degree of competitive intensity in the market. In a sense, every company has a monopoly of its own product, since no one else makes exactly the same product. Differentiated products are not necessarily *better*, in an objective sense, than others; they are simply designed to appeal to a particular market niche.

Successful product differentiation moves products from competing primarily on price to competing on nonprice factors. The opportunities for product differentiation exist with the physical qualities of the product itself, as well as within the total package of benefits offered to the customer. These benefits could include elements such as differences in quality (usually accompanied by differences in price), differences in availability (such as time and location), packaging, service, installation, training, customization, brand image, accompanying products or services,

the manner in which the product is delivered, and many other possibilities. Indeed, the opportunities for product differentiation are limited only by the imagination and creativity of marketers.

The importance of product differentiation actually increases when the core product offering is undifferentiated. Undifferentiated product offerings are essentially commodities, and if treated as such, do not require any marketing actions. One of the most important reasons the marketing function exists is to continuously decommo-ditize products, so that they offer differential value to different customers based on their unique needs and requirements.

It is helpful to think of a product as not a simple object but as a “complex cluster of value satisfactions,” as Theodore Levitt put it. His “total product concept” consists of the generic product, the expected product (which includes the minimal attributes necessary in order to acquire any customers at all), the augmented product (which goes beyond the bare minimum requirements to include value-added elements that have different levels of appeal to different customers), and the potential product (which refers to additional ways to create value that remain possible, but have not yet been attempted).

Over time, many products that used to be sold as commodities have become highly differentiated offerings. Examples of foods include coffee, salt, flour, sugar, salt, oatmeal, bananas, chicken, pineapples, and many others. Relatively homogeneous services such as banking, insurance, credit cards, and air travel have become differentiated as well.

Product differentiation goes hand-in-hand with other central concepts in marketing such as MARKET SEGMENTATION AND TARGETING and marketing targeting and positioning (*see* POSITIONING ANALYSIS AND STRATEGIES). Product differentiation must be purposeful, in that it creates additional tangible and intangible value for the customers for whom the product is intended. Differentiating a product generally adds to the cost of producing it, and this cost must be more than offset by the additional value that is created for customers, and for which they are willing to pay a premium.

positioning analysis and strategies

U. N. Umesh

Positioning is the act of designing an organization's offering and image so that it occupies a distinct and valued place in the target customer's mind relative to competitive offerings (Kerin and Peterson, 2007; Ries and Trout, 1982). The result of positioning correctly is the creation of a customer-focused value proposition (Kotler and Keller, 2006). Successful positioning requires that the similarities and dissimilarities between brands should be clearly defined and communicated in a target market for a particular category (see PRODUCT CATEGORY) or service. Further, the customer should find the position believable; otherwise the firm will never achieve its intended positioning in the minds of the customers who may even be turned off by the unrealistic positioning message. Given the specific nature of positioning, and the diversity of a market, it is increasingly difficult to create a brand position that appeals to everyone in all usage circumstances. Coca-Cola might have been one of the few firms that achieved universal appeal in the first half of the twentieth century using a very broad-based positioning for its single product brand. However, over the years, even Coca-Cola was forced to create separate formulations and unique positionings for those who preferred diet, orange or lemon-flavored product, and so on.

Positioning is of particular relevance in a global context (see GLOBAL MARKETING STRATEGY). Though the markets in industrialized countries are large, they are growing at a much slower pace as compared to those in developing countries. Not only are the markets in the two most populous countries in the world – India and China – growing at a rapid pace but numerous smaller countries with their widely different cultures are also growing at similar rates because of the advent of globalization and the unleashing of free markets. There are numerous global brands that appear to be successful in almost all markets (Helm, 2008). Quelch (2007) has suggested that having a single and consistent positioning worldwide with the company name and brand name being the same is the surest recipe for success – with a focus on a single product category. In contrast, Reibstein

and Day (2004) suggest that it might be wise to have different levels of globalization providing some degree of local adaptation. As an example, food products should meet local cultural tastes in terms of branding.

An ideal positioning strategy is not necessarily achieved by aiming for the highest evaluative position in the minds of the customer. Rather, it is important that the positioning offered should match expectations of the customers in terms of the ideal attribute levels desired by the customers. Many firms are successful with a low-price/medium-quality brand image while other firms are equally successful with above-average price/high-quality brand image.

Mispositioning can occur when there is a mismatch between the ideal attribute levels desired by the customer and those offered by the firm. Usually, it is a positioning that the firm would like the customer to have, rather than what the customer actually desires. An example is the introduction of dry beer, which was rated as superb by brewers, where the customers had a hard time understanding how dryness of a beer could possibly quench the thirst of a parched throat.

Over time, the ideal attribute levels desired by the customers change. These changes could be due to advancement of technology, acceptance of new cultural values, changes in demographics, or improvements in competitive (see COMPETITIVE ANALYSIS) offerings. If there is no concomitant change in positioning, then the firm, product, or brand goes into the decline phase and can disappear altogether over time. Thus, there is a need to constantly evaluate and change positionings over time to match changes in customer requirements.

pricing strategy

R. Venkatesh

INTRODUCTION

Marketing efforts revolve around the concept of value, especially as perceived by customers. Specific branches within marketing examine the magnitude of customers' perceived value of goods or services, the sources or drivers of value, and the ways and means of delivering better value to the customer and to the firm. Pricing and other marketing mix variables are strategic aids for a manager in the value creation and management process.

It is often noted that while product development, advertising, and distribution convey or deliver value to the customer, pricing emphasizes delivering value to the firm (i.e., extracting value from the customer). While this belief is largely correct, the interaction and interplay within the marketing mix cannot be overlooked. Thus, while one could consider changing prices in isolation of other factors, a better approach would be to implement price changes in tandem with other modifications to the value proposition (*see* A FRAMEWORK FOR CREATING VALUE PROPOSITIONS). As an example, a price increase on a Toyota Prius could be tied to commensurate improvements in the vehicle's fuel efficiency. Such an approach underscores what pricing truly is: an integral component of a firm's overall value proposition.

This article on pricing strategy is introductory in nature and has the following orientations. *First*, the article attempts to layout and connect the key elements in the pricing process. Pricing terms are introduced on a selective basis. *Second*, strategic pricing implications and recommendations are provided in almost every section. In contrast to strategies, tactical aspects of pricing (e.g., sales promotion tools such as "couponing") get limited attention. *Third*, some of the relatively more recent trends in or challenges to pricing are examined. Price taking as opposed to price setting (priceline.com) and auctions (eBay) are among the Internet-driven topics discussed. Throughout this article, goods and services are collectively referred to as *products*.

Among the strategic implications proposed in this article are the following:

- Value pricing is the desirable pricing approach. It overcomes the myopia of cost-plus and going-rate pricing without losing sight of costs and competing offerings.
- Product differentiation is a prerequisite for value pricing. Commodities drive prices down to marginal costs.
- A decreasing price is often more desirable than an increasing price path. High initial prices can signal superior product quality when other information is limited.
- While most price discrimination (PD) strategies are legal, the seller should not lose sight of price transparency and fairness.
- The Internet is opening up exciting and profitable avenues for pricing.

The emphasis on breadth and brevity means this article only serves to introduce the domain of pricing to the reader. Several books and numerous articles, from both the managerial and academic realms, are available for the interested reader. Some of these are listed in the concluding section. The ideas, concepts, and methods discussed in the following pages are drawn from or inspired by many sources. Per the policy of the editors, only a few references are cited explicitly. Kotler and Keller (2008), Nagle and Hogan (2005), and Rao (2009) are among the sources consulted most often during the writing of this article.

The remainder of this article has the following structure. Setting the initial price of a product is discussed in the section "Setting the Price." Managing this price over time and across segments are considered in the sections "Managing The Price Over The Life Cycle" and "Varying The Price Across Segments," respectively. The influence of competition on price setting is examined in the section "Anticipating And Responding To Competitors' Price Changes." The interrelationships among products in a firm's portfolio and their impact on the pricing of a particular product are discussed in the section "Pricing A Portfolio Of Complements Or Substitutes." The section "Pricing and the Internet" focuses on Internet-driven

2 pricing strategy

pricing trends and challenges. A chapter summary appears in the “Conclusion” section.

SETTING THE PRICE

Price setting requires an appreciation of both the product and the market. For illustration, the success of repeat purchased goods, sometimes called *FMCGs* (*fast moving consumer goods*), depends on both trial and repurchase. Pricing practices that facilitate brand loyalty have merit. The seller of FMCGs can gain access to rich datasets such as scanner panel data as part of setting the prices. In contrast to FMCGs, durable goods are purchased with long inter-purchase times and typically after significant information search and consideration. On the market side, the nature of heterogeneity across customers in taste, brand preference, purchase incidence, and cognitive/monetary resources plays an important part in price setting. These types of factors will require adjustments to the price-setting process described below.

Eliciting or estimating individual value or aggregate demand is a prerequisite to price setting. The demand function, namely, the representation of the units of a product demanded at different price points, is often calibrated in a linear or curvilinear form as shown in Figure 1.

With two competing products 1 and 2, the linear demand function for 1 takes the form

$$Q_1 = a_0 + a_1 P_1 - a_2 P_2 \quad (1)$$

where the P s and Q represent prices and quantity. Coefficient a_1 (or a_2) represents price sensitivity, namely, the change in quantity demanded

of product 1 when P_1 (or P_2) is changed by one currency unit, holding all else constant. The constant elasticity demand function has a curvilinear form. Again, with two competing products 1 and 2, the demand function for 1 is

$$Q_1 = a_0 P_1^{\varepsilon_1} P_2^{\varepsilon_2} \quad (2)$$

where the P s and Q continue to represent prices and quantity. The exponent ε_1 represents the self-price elasticity of demand of product 1 and ε_2 is cross-price elasticity of demand of product 1 with product 2. In either case, elasticity refers to the percentage change in quantity demanded for a 1% change in price. Typically, self-price elasticity is negative (i.e., an increase in a product's price causes its demand to decrease) whereas cross-price elasticity is positive (i.e., an increase in a competitor's price causes the focal product's demand to increase). The choice between the above two functional forms can be on the basis of goodness of fit between historical price and demand data.

When the marginal cost of product 1 is c_1 , and given the price of the competing product, the profit-maximizing seller can set the price P_1 such that

$$\text{Max}_{P_1} \prod_1 = (P_1 - c_1) \times Q_1 \quad (3)$$

This again assumes that the seller seeks profit maximization in each time period. (The competitor is also strategic and that requires understanding the best response of each firm and the resulting equilibrium. This is taken up in the section “Anticipating And Responding To Competitors' Price Changes.”) Other objectives such as setting the best price to sell a targeted quantity or maximizing the net present value of a stream of profit flows can all be achieved with a proper understanding of demand.

The above approach to price setting assumes a clear knowledge of (i) customers' valuations or purchasing behavior, (ii) firm's cost structure, (iii) competitors' prices and intentions, and (iv) product interdependencies. Such a comprehensive knowledge may not always exist. Alternative approaches are discussed below.

Cost-plus (or markup) pricing and going-rate (or competitor-based) pricing are more prevalent than what sound strategy might dictate. In

Figure 1 Two popular forms of the demand function.

Table 1 A simple illustration of value pricing.

| (This is a fictitious example) | | |
|---|----------------|--------------------|
| A chemical plant uses 400 O-rings each year to seal valves. Rings are priced at \$8.00 each and must be changed every two months in a shutdown process that costs \$8000 (including the labor cost of replacing the rings). Our firm has developed a new O-ring that has twice the resistance to corrosion. The marginal cost to our firm of the new O-ring is \$5. There are no other alternative O-rings in the marketplace. What is the economic value advantage of each new O-ring? | | |
| Let the price of each new O-ring be P | | |
| Description | Regular O-Ring | New O-Ring |
| Number of rings needed | 400 | 200 |
| Purchase price to the customer | \$3 200 | $200 \times P$ |
| Shutdown costs | \$48 000 | \$24 000 |
| Total costs to the customer | \$51 200 | $\$24\,000 + 200P$ |

Economic value advantage of each new O-ring = $\frac{\$51200 - \$24000}{200} = \$136$. Our firm would not want to charge a price lower than \$5 for the new O-ring as that would yield a negative unit contribution margin. \$136 is the unit price at which the customer would be indifferent between the regular and the new O-rings. The actual price is likely to be between these extremes and based on other considerations such as the likelihood of new entrants at different candidate prices.

cost-plus pricing, the firm adds a markup to the unit cost of the product. Going-rate pricing considers the price charged by the leading (or closest) competitor, with some upward or downward adjustment based on whether the firm is a price leader or follower. Both of these approaches are easy to implement yet deeply flawed. The ease arises from the firm’s knowledge of its own cost structure and/or the prices of competing offerings. The problems arise from taking a very passive and myopic view of pricing and marketing, namely, that the firm takes its cost and competitors’ prices as a given and is not actively seeking to differentiate its offering and enrich its value proposition.

Value pricing is arguably a superior alternative as it balances firm’s costs, value of competing offerings, and the incremental value of the product under consideration. Thus

$$\begin{aligned} &\text{Perceived value to the customer} \\ &= \text{Reference value} + \text{Differentiation value} \end{aligned} \tag{4}$$

The reference value is the net value of the closest substitute. The differentiation value represents whatever value the focal product

offers above and beyond the reference product. This assessment of value considers all the sources of benefits and costs (tangible and intangible) to the customer. Table 1 contains a simple illustration with higher value equated to lower costs.

In the table, the term *economic value advantage (EVA)* represents the differentiation value without factoring in the price of the new offering – the decision variable in this exercise. The portion of the EVA to extract in the form of price will depend on the firm’s strategic priorities.

An added advantage of value pricing is that it can be used even to price radical innovations (e.g., the MRI machine, when it was first introduced). Such innovations have weak substitutes (e.g., CT scan in lieu of MRI). Thus, while the technology is new, the benefit can be quantified on the basis of what the available substitute does or does not offer. Techniques such as conjoint analysis augment value pricing by looking at attribute-level value drivers.

The term *reservation price*, defined as the maximum price a customer is willing to pay for one unit of a product, is a currency metric of the customer’s perceived value. The difference between a customer’s reservation price and the actual price of the product represents his or her

4 pricing strategy

surplus. When a product enjoys a monopoly, the prospective customer is expected to buy the product if she/he expects a nonnegative surplus. When competing products are available, the customer is expected to choose the product that offers the highest nonnegative surplus.

MANAGING THE PRICE OVER THE LIFE CYCLE

THE STAGES OF THE PRODUCT LIFE CYCLE is a potent marketing paradigm to conceptualize the evolution of alternative products and draw strategic implications over time. A successful product goes through four stages in its life cycle – introduction, growth, maturity, and decline. Sales during maturity come primarily from product replacement. The length of each stage is partly a function of the characteristics of the product and of potential consumers such as their attitudes toward risk and the level of word of mouth among themselves. Seen from a pricing standpoint, a firm can “manage” the adoption by choosing from among alternative price trajectories. Such variation of price over time is called *dynamic pricing*.

Skimming and penetration pricing are two alternatives to a more neutral form of pricing. With skimming, the firm starts by charging a high price and then gradually decreases it over time. This could be very profitable for durables: the decreasing price path could extract the most value from customers, assuming that customers will not delay their purchases inordinately in anticipation of lower prices in the future. With penetration pricing, the product is initially priced aggressively low to encourage speedy adoption. How the price is changed later is a function of other variables to be discussed. The choice in favor of skimming or penetration pricing in relation to neutral pricing depends on variety of firm-, competitor-, and customer-side factors.

Skimming is a more desirable under the following conditions:

- *Firm-side factors:* When a firm has a wide product line (e.g., Intel, with its range of microprocessors), a new product can be priced high enough so as not to cannibalize other offerings in the line. Also, a firm's

capacity constraint naturally lends itself to skimming.

- *Competitor-side factors:* Skimming is not only a more time-intensive strategy (as the market is built gradually, over time) but also the higher price might signal low barriers for entry. Therefore, skimming is more desirable only when the firm has a clear technological advantage (e.g., Apple with iPhone) or patent protection to milk the market over time.
- *Customer-side factors:* Greater heterogeneity in customers' valuations and the willingness within segments to pay significant premiums for their “ideal” products favors skimming. It is desirable that price skimming is not excessive and is not seen as unfair. This occurred with HIV Aids medication, for example, when the high initial price of the drug cocktail (over \$10 000 per patient per year) caused a furor from the developing world. Global prices quickly dropped to under a dollar a day per patient.

Conditions opposite to the ones noted above for skimming are likely to favor penetration pricing. The following additional factors also point to a low penetration price:

- *Firm-side factors:* Penetration pricing is desirable when a firm expects significant gains from economies of scale. Also, for experience goods such as software, an extreme penetration pricing approach of offering a free initial version to gain a foothold and a later upgrade at a higher price may be optimal.
- *Competitor-side factor:* When two competing systems are in a standards war, the one that establishes a larger user base would arguably emerge a winner. Penetration pricing could facilitate this. The lower price of Toshiba's HD DVD system during its losing battle with Sony's BluRay DVD format stands out as one of the exceptions.
- *Customer-side factor:* For products with network externalities, the value to individual users is a function of the number of other users of the product. A low initial price to build the network followed by a higher price

later in the life cycle has been suggested as an optimal strategy.

Every-day-low-price (EDLP) and high-low (Hi-Lo) pricing are also forms of dynamic pricing. As these are not tied to the product life cycle paradigm and are of a tactical nature, these are not discussed further in this article.

VARYING THE PRICE ACROSS SEGMENTS

While a firm should strategically arrive at a price for its core segment of users, a one-price-fits-all approach toward the entire market is seldom the most profitable. Segments differ in their preference intensities for the product, in their income levels and price sensitivity, quantity of consumption, and the like. Price discrimination (PD) is a desirable strategy in such instances and is said to occur “when a company sells a [good] or service at two or more prices that do not reflect a proportional difference in costs” (Kotler and Keller, 2008).

While three degrees – or types – of PD have been identified, these differ in the ease of implementation. Under first-degree PD, the seller charges each customer a price equal to her reservation price. Of course, only those customers with reservation prices higher than the product's marginal cost are targeted. When possible, this type of PD should be the most profitable for the seller as the entire surplus is extracted. Two common hurdles to first-degree PD are the seller's lack of awareness of each customer's reservation price and the inability to charge different prices without upsetting customers' perceptions of fairness. Auctions are one way of implementing first-degree PD. If bids are invited and one or more units of the product are sold to the highest bidder(s), the seller is arguably extracting the full surplus from at least the winning bidder(s). Singapore Airlines' auction of seats on the first commercial flight of the Airbus A380 Super Jumbo, between Singapore and Sydney, can be called first-degree PD. Here, interested fliers submitted bids on eBay and tickets priced on par with the respective bids were awarded to the highest bidders till all seats were sold out.

Second-degree PD occurs when the seller offers different prices to different buyers based

on their purchase quantity. An objective of this form of PD is to encourage buyers to purchase in larger volume. The law of diminishing marginal returns is an associated rationale for second-degree PD. As a second or third unit gives less utility to the consumer than the first, discounts are warranted on these latter units to facilitate purchase. In an excellent review article, Dolan (1987) contrasts the uniform price schedule (i.e., no PD, as each unit is sold at the same price) from n -part and n -block price tariffs. In a simple two-part tariff ($n = 2$), each buyer pays a fixed fee plus a variable rate tied to the number of units purchased. This tariff structure reduces the unit price for a large purchase because the fixed fee is apportioned over a larger number of units. Telephone calling plans and some types of software licenses come under this category. In a two-block tariff, a price P_1 is charged for each for the first N units; a price $P_2 (< P_1)$ is charged for each unit beyond N . The three-part or three-block tariff should price discriminate at least as well as a two-part or two-block tariff. The issue to guard against is customer confusion from too fine a structure.

Third-degree PD occurs when the distinctive aspects of customers (e.g., senior citizen vs. young adult) or shopping occasions (e.g., matinee vs. regular show) form the basis for charging different prices. Unlike second-degree PD, the quantity of purchase is not the discriminating variable. Unlike first-degree PD, the differences in reservation prices are not known for sure. Rather the expectation is that some groups of buyers may have lower (or higher) reservation prices. Senior citizens and students who probably do not have full-time jobs are likely to have more available time or less disposable income, thereby making themselves appropriate targets for price discounts. For services (e.g., flights), that are cannot be inventoried unlike physical goods, and for offerings subject to capacity constraints (e.g., concerts), third-degree PD may help in managing demand (by shifting part of the peak load to off-peak times).

Although there are legal restrictions on some forms of PD (e.g., some types of quantity discounts must be backed by evidence of associated cost savings to the seller), most forms of PD are legal and hence widely used. Constraints to PD may arise from the buyer side. PD will be

6 pricing strategy

rendered ineffective or inappropriate if, say, it is perceived as blatantly unfair or if those buying the products at a lower price sell these to others who might not have qualified for the discount (a practice called *arbitrage*). In most situations, PD actually increases customer welfare by making products available at lower prices to specific groups and increasing consumption.

ANTICIPATING AND RESPONDING TO COMPETITORS' PRICE CHANGES

The role of competition can never be overemphasized. Be it an entrenched player or a capable new entrant, competitors are “hurdles” in a firm’s pursuit of higher profits. By the same token, healthy competition results in better value for customers by fostering innovation, keeping prices under check, and tailoring marketing practices to suit the needs of specific segments.

Work on competitive strategy (Porter, 2005) and game theory (Dixit and Nalebuff, 1993) provides ways to understand competitors’ incentives and motives, and take preventive, protective, or reactive measures (*see* also COMPETITIVE ANALYSIS; COMPETITOR

ANALYSIS). Table 2 contains a simple illustration of game theoretic thinking that has the following elements: (i) the players are aware of each other’s strategic options and the corresponding payoffs; (ii) each player recognizes that the competitor is not static but behaves strategically; (iii) each player acts in one’s own best interests knowing that the other player does the same; that is, benefiting oneself rather than hurting the other is the overriding motive.

The illustration underscores that while higher prices from the two players would have provided higher payoffs for both, thinking strategically about each other in a noncollusive manner leads to a lowering of prices. The example shows how the free market can work to the customer’s advantage.

There is also a limitation in the above approach. The illustration assumes that price is the only variable at the firms’ disposal at this stage of the game. A broader marketing view of this problem could consider nonprice ways of mitigating the intensity of competition. Echoing this thought, Porter (1998) notes that there are essentially two competitive strategies: gaining cost advantage or pursuing differentiation. The

Table 2 Pricing under competition: a simple illustration.

| (The numbers are made up) | | | |
|--|--------------|-----------------------------|----------------|
| Ford and General Motors (GM) are the two dominant competitors in the B2B market to sell cars to rental car companies. This business segment is marked by aggressive price discounting unlike the end user market. The discounts are usually either 15% or 20% off the maximum suggested retail price (MSRP) in the retail market. The players do not collude in any way; they play the Leader (GM)–Follower (Ford) game. That is, GM sets its discount rate first. Ford sees it and immediately comes up with its best response. The payoff matrix is given below. | | | |
| | | GM's Discount | |
| | | 15% off MSRP | 20% off MSRP |
| Ford's discount | 15% off MSRP | \$360M, \$640M ^a | \$180M, \$410M |
| | 20% off MSRP | \$420M, \$240M | \$210M, \$350M |

^aMeans that Ford’s payoff is \$360 million and GM’s payoff is \$640 million. What discount levels are Ford and GM likely to offer at the equilibrium? Why? In this example, the equilibrium corresponds to GM offering a 20% discount and Ford responding to it with a 20% discount. The reasoning is as follows: no matter what discount GM offers (15% or 20%), Ford’s best response is a 20% discount. This is because (i) when GM offers a 15% discount, Ford makes \$420M with a 20% discount instead of \$360M with a 15% discount, and (ii) when GM offers a 20% discount, Ford makes \$30M more for itself with a 20% discount relative to a 15% discount. Knowing that Ford’s best response is a 20% discount, GM will offer a 20% discount as it will make \$350M (i.e., \$110M more than with a 15% discount). With both firms offering a 20% discount, neither will have a unilateral incentive to deviate, and this discount combination will represent a Nash equilibrium.

firm with the lowest cost structure in its industry (e.g., Southwest Airlines) has a greater ability to fight a price war. Everyone else is better off pursuing differentiation.

Price wars represent the uglier side of pricing, the competing sides emerging losers in the fight. Rao, Bergen, and Davis (2000, RBD) point out that from the firm's side, the best approach to a price war is often not to get into one. In the guidelines below on how to avoid a price war or mitigate the effects of one, those from article by the Rao *et al.* are tagged RBD:

- *If a competitor attacks you in your backyard, signal your intent by attacking the competitor in its backyard:* The example of Michelin, with its European stronghold, initiating a price war against Goodyear in its prime US market is well known. Goodyear responded by cutting prices in Europe, signaling to Michelin that it stood to lose considerably. The price war subsided.
- *Reveal your cost advantage to your competitor (RBD):* The authors make the point that revealing this advantage will make the competitor aware that you have more room to cut prices and still make a positive contribution.
- *Buy excess capacity in your industry and shutter the plants:* Industries with excess, idle capacity are prime candidates for price wars. Try to reduce this excess.
- *Introduce a fighting brand (RBD):* Offerings such as MCI Worldcom's 10-10-220, Kodak's Funtime film, and Goodyear-owned Kelly Springfield tires are examples of high-quality firms introducing lower-end fighting brands to handle price competition without exposing the flagship offerings to the fight.

The above points underscore that pricing strategies have more power when firms are willing to tap into their broader marketing options.

PRICING A PORTFOLIO OF COMPLEMENTS OR SUBSTITUTES

There are few single-product firms even though many a firm may have a single blockbuster.

Products in a firm's portfolio could be (partial) substitutes of each other when they are part of a product line (e.g., the line of soft drinks offered by Coca Cola). When a firm is in multiple categories, the products could be complements of each other (e.g., Samsung's DVD player is a complement of the firm's TV lines). This section makes the point that pricing strategies are more potent and meaningful when the interrelationships among the offerings are suitably leveraged. The degree of substitutability or complementarity among the offerings has strategic significance.

Cross-price elasticity is one measure of the degree of interrelationship. Two products are complements of each other when their mutual cross-price elasticities are negative; that is, an increase in the price of one causes a decrease in demand for the other. Cross-price elasticities between two substitutes are positive. Another measure is by how much the reservation price of a bundle is greater than (or less than) the sum of the stand-alone reservation prices of the individual products. For a bundle of complements (or substitutes), the reservation price of the bundle is greater than (or less than) the sum of the individual reservation prices.

Consider a product line of moderate to weak substitutes. (Having two strong substitutes in a firm's product line is arguably suboptimal.) There is evidence to suggest that with a wider product line, the price of each product is typically higher relative to the case when that product alone is offered. The rationale is that with several offerings, each can be targeted at the segment that it is best suited for. The match with the segment's ideal point justifies charging a higher price. A product line is also justified as a way to keep up with an evolving market. Considering again the example of the line of Intel microprocessors for personal computers, the firm cuts prices of existing microprocessors as newer ones are introduced at high price levels. Discounting the more established processors is a bulwark against competitors. Thus, the line remains very profitable while also protecting the firm's market share.

For a portfolio of complements, **BUNDLING** is pertinent. *Bundling* is the strategy of offering of two or more products as a specially priced package. Bundling encourages customers to

try the complementary products jointly. The synergy among complements means customers see higher value and the firm can tap into some of this value enhancement. Three bundling strategies must be distinguished. Under pure components, the products are offered separately but not in bundled form. Pure bundling occurs when the products are offered only as a bundle but not in stand-alone form. Mixed bundling is the more general strategy of offering both the individual products and the bundle. This strategy helps achieve second-degree PD by offering the discounted bundle at the segment that cares for all of the component products, and charging price premiums on the individual offerings.

The choice among alternative bundling strategies is further clarified below:

- *Firm-side factors:* Pure bundling is favored when it can significantly reduce inventory holding costs (e.g., a car model offered in a few popular trims instead of many attribute combinations) and/or sorting costs (e.g., raw diamonds, sold as bundles by DeBeers).
- *Competitor-side factors:* Although pure bundling could deter competition in some instances, the pure components strategy is desirable when customers' strongly preferred bundle is a mix of offerings from rival firms (e.g., Dell PC with HP laser printer).
- *Customer-side factors:* Mixed bundling, the equivalent of a wider product line, is desirable when customers' preferences are very heterogeneous. Pure bundling is desirable when it is harder for a customer to identify the cause when a bundle performs poorly. Otis encourages customers to opt for its own service plan because, if the product breaks down because of poor maintenance by another service provider, customers may still blame Otis for the problem.

product specifications; (ii) blogs and social networking websites disseminate word of mouth with speed and on a large scale; (iii) products that can be digitized, such as movies and music, can also be pirated; (iv) magazines and newspapers are threatened by the large amount of free news content. Yet the Internet has spawned entirely new businesses and business models that depend on clever pricing strategies. A core component of any business plan is the revenue model – a clarification of how the firm expects to price and make money.

Two online business models with innovative pricing arrangements are discussed here:

- *Name your own price:* The emergence of Priceline.com (among others) has meant that the Internet has made pricing buyer driven rather than seller driven. The buyer submits a bid for a product such as an airline ticket between two cities, and the seller decides whether to accept or reject the offer. Thus the seller becomes a price taker instead of being a price setter. Frivolous bidding is limited by imposing restrictions on rebidding. The Priceline model cleverly combines pricing and product design. While a bidder quotes a price, it is up to the seller to select the airline and specific schedule.
- *Auctions:* eBay has made auctions a household name. By establishing a trading platform, trading rules, and mechanisms, eBay has dramatically increased the number of sellers and the way they sell. Network externalities are integral to auctions: an auction site is more attractive to a buyer (or seller) if it attracts more sellers (or buyers) than a competing site. By facilitating these connections, eBay is increasing revenues to sellers while simultaneously delivering greater value to the buyers.

The Internet's role in pricing and marketing is just beginning.

PRICING AND THE INTERNET

The Internet provides new and exciting pricing opportunities and challenges (see E-COMMERCE AND INTERNET MARKETING). The challenges come in several forms: (i) prospective consumers can easily and quickly compare prices and

CONCLUSION

This article has sought to provide a broad yet cursory overview of the strategy of pricing. It has introduced and discussed pricing terms that are frequently invoked. The article has also

emphasized that an effective pricing strategy often draws on other elements of the marketing mix. For setting and managing the price of a product many elements such as the segments in the marketplace, the intentions and actions of competitors, the interrelationships with other products in the portfolio, and the power of new technology and channels such as the Internet have to be considered. A number of strategic implications have been discussed. Yet this article is incomplete. The following paragraphs suggest the notable omissions in this article and suggest some ways of gaining a deeper understanding of pricing.

The pricing implications of consumer psychology and behavior (*see* CONSUMER BEHAVIOR ANALYSIS) have barely been noted in this article. Prospect theory, for example, focuses on how customers respond differently to losses and gains. The price of a product represents a cost to the customer. Rebates and discounts can be seen as gains. Related implications of prospect theory can guide how prices and discounts should be framed to have more favorable impact. This article has barely scratched the surface on the topic of channel pricing. As intermediaries, channel members can cause an increase in product prices even while providing important services. The success of emerging channel structures (*see* MARKETING CHANNEL STRATEGY) such as partial forward integration and bricks-and-clicks outlets depends in part on appropriate pricing. The intertwined concepts of customer lifetime value and customer relationship management require taking a relationship perspective to marketing mix efforts, including pricing. Pricing methodologies span the spectrum from measurement of customers' valuations to multiproduct pricing under competition. These and other topics are missing in this article.

A short list of references at the end of this article can offer the reader a more in-depth view of pricing. Most of the references are aimed at managers. Two references for the theoretically driven reader are Rao (2009) and Wilson (1993). Marketing journals such as the *Journal of Consumer Research*, *Journal of Marketing*, *Journal of Marketing Research*, and *Marketing Science* are recommended for rigorous studies on pricing. The *Harvard Business Review* is one of the several publications taking a managerial

view of emerging topics. Nuances in pricing and related marketing of digital products are discussed in Shapiro and Varian (1998). Pricing strategy is an exciting and important aspect of global marketing (*see* INTERNATIONAL PRICING OBJECTIVES AND STRATEGIES). Mahajan and Banga (2005) provide an insightful reference on the opportunities and challenges of marketing to the 86% of the world's population that lives in the developing world. The above references can facilitate a greater appreciation of the fascinating topic of pricing.

product category

Jaeseok Jeong

The term *product category* is given to a group of similar products that fulfill a particular type of need and can be interchangeably used with product class. A group of products or brands in the same product category are homogeneous or generally considered as substitutes for each other. For example, Levi's and Gap belong to the jeans category and one can be a good substitute for the other. They both can meet consumers' particular need for jeans.

A products is generally identified in terms of its product category, which can be defined as the classification to which the product is assigned. For example, Special K is the breakfast cereal category and MacBook Air is in the notebook computer category. There are variations among products within a category in terms of physical characteristics (e.g., color, shape, attribute, or fragrance) or brand names. A single manufacturer may produce several brands within the same product category in order to appeal to different segments of the market. For example, Apple has multiple notebook computer brands such as MacBook, MacBook Pro, and MacBook Air in the same notebook category and markets these brands to different segments of its target customers to maximize its profits.

The product category can be narrow or broad depending on how substitutable the various products are. For instance, a narrow product category for a transportation vehicle would include motorcycles, cars, pickups, and vans, whereas a broad product category would include airplanes, trains, and ships. Another example is that a narrow product category for breakfast meats might be sausage, bacon, and ham and a broad product category would include all other meats and meat substitutes occasionally sold for breakfast use.

The identification of product category can sometimes be ambiguous and even arbitrary and this can be an issue for marketing managers in measuring the market performance and understanding the market structure and competition for their own product(s). If you are a marketing manager in a company producing breakfast meats, would you think that you are in

the breakfast meats category and your competitors are all other (or similar) brands in the same product category or would you consider all other meats or meat substitutes brands including breakfast meats as competitors? In other words, are you in the breakfast meats category or in the meats and meat substitutes category? Your marketing strategy would be dramatically different depending on how you see your product category.

This inherent ambiguity and arbitrariness on the product category have led to debates on how it should be defined to better comprehend the market and its structure (Hanan, 1974; Moran, 1973). Day, Shocker, and Srivastava (1979) proposed that marketers focus on the benefits that products provide instead of the attributes or features that products have in identifying the product category. They recommended that the product category be defined as "the set of products judged to be substitutes within those usage situations in which similar patterns of benefits are sought, and the customers for whom such usages are relevant." By doing so, marketers could have a better understanding of the market and its structure and arrive at effective criteria of measuring the market performance and competition.

A product category tends to have a STAGES OF THE PRODUCT LIFE CYCLE that is longer than that of any one product within the product category alone unless a particular brand that was the FIRST-MOVER (PIONEER) ADVANTAGE in a market was also the last one.

Category development index (CDI), a market's category sales percentage divided by the total population percentage of that market multiplied by 100, and brand development index (BDI), a market's brand sales percentage divided by the total population percentage of that market multiplied by 100, are useful to determine market potential for a brand or product. Any number over 100 for the CDI and BDI is considered good but comparing the BDI to the CDI offers the most insight.

Primary advertising, also known as *generic advertising*, is the advertising intended to create demand for a product category of a product rather than a specific brand and to enhance the image of the entire product category involved. The campaign, "Got Milk" by California Milk

2 product category

Processor Board would be a good example of primary advertising. Primary demand is the demand for a general product category, as contrasted with selective demand, the demand of a specific brand marketed by a firm.

stages of the product life cycle

Jaeseok Jeong

The product life cycle (PLC) is a biological metaphor that traces the stages of a product's acceptance from its introduction (birth) to its decline (death). It can be divided into several stages characterized by the revenue generated by the product. The product revenue and profits can be plotted as a function of the life cycle stages as shown in Figure 1.

The concept of PLC may apply to a brand or to an entire PRODUCT CATEGORY. Its duration may be as short as a few months for a fad item or century or more for product categories such as the cola beverage and the gasoline-powered automobile. As the product progresses through its life cycle, changes in the MARKETING MIX are usually required in order to adjust to the evolving challenges and opportunities.

INTRODUCTION STAGE

When the product is introduced, sales will be low until customers become aware of the product and its benefits. During the introduction stage, the firm aims to build awareness and develop a market for the product. The impact on the marketing mix is as follows:

Product – There is one or few products, relatively undifferentiated in the market. Product branding and quality level is established.

Price – Pricing (*see* PRICING STRATEGY) may be high, assuming a skim pricing strategy for a high profit margin as the early adopters buy the product and the firm seeks to recoup development costs quickly. In some cases, a penetration pricing strategy is used and introductory prices are set low to gain market share rapidly.

Distribution – Distribution is selective and scattered as the firm commences implementation of the distribution plan.

Promotion – Promotion is aimed at building brand awareness. Samples or trial incentives may be directed toward early adopters. The introductory promotion is also intended to convince potential resellers to carry the product.

Figure 1 Several stages of product life cycle (PLC) can be characterized by the revenue over time.

GROWTH STAGE

During the growth stage, sales increase as more customers become aware of the product and its benefits and additional market segments are targeted. The firm seeks to build brand preference and increase the market share.

Product – Product quality is maintained and additional features and support services may be added.

Price – Pricing (*see* PRICING STRATEGY) is maintained at a high level if demand is high, or reduced to capture additional customers.

Distribution – Distribution becomes more intensive. Trade discounts are minimal if resellers show a strong interest in the product.

Promotion – Advertising is increased to build brand preference.

MATURITY STAGE

The maturity stage is the most profitable. While sales continue to increase into this stage, they do so at a slower pace. Competition may appear with similar products. The primary objective at this point is to defend market share while maximizing profits and extend the PLC.

Product – Modifications are made and features are added in order to differentiate the product from competing products that may have been introduced.

Price – Price reductions are expected in response to competition while avoiding a price war.

Distribution – Distribution becomes more intensive and incentives to resellers may be offered to avoid losing shelf space.

2 stages of the product life cycle

Promotion – Promotion emphasizes product differentiation and building of brand loyalty.

DECLINE STAGE

Eventually, sales begin to decline as the market becomes saturated. At this stage of the PLC, the firm has several options. First, the firm maintains the product and rejuvenates it by adding new features and finding new uses. Second, the firm harvests the product by reducing costs and continuing to offer it, possibly, to a loyal niche segment. Lastly, the firm discontinues the product when no more profit can be made or there is a successor product. The MARKETING MIX decisions in the decline stage depend on the selected strategy. For example, the product may be changed if it is being rejuvenated, or left unchanged if it is being harvested. The price may be maintained if the product is harvested, or reduced drastically if liquidated.

The term *life cycle* implies a well-defined cycle as observed in living organisms, but products do not have such a predictable life, and the specific life cycle curves followed by different products vary substantially (Dhalla and Sonia, 1976; Day, 1981). Hence the life-cycle concept is not well suited for the forecasting of individual product sales. Furthermore, critics have argued that the PLC may be self-fulfilling. For example, if sales peak and then decline, marketing managers may conclude that the product is in the decline stages and therefore cut the promotion budget, thus precipitating a further decline.

Nonetheless, the PLC concept helps marketing managers to plan alternate marketing strategies to address the challenges that their products are likely to face. It also is useful for monitoring sales results over time and comparing them to those products having a similar life cycle.

push and pull marketing strategies

Deanne Brocato

A push/pull strategy refers to the way in which information and products move between consumers and a manufacturer. Specifically in marketing, this strategy refers to the focus of the promotional efforts used to sell a good or service. In a push strategy, suppliers “push” their goods toward consumers, and in a pull strategy consumers “pull” information or goods that are suitable for their needs. A *pull strategy* is defined as a promotion strategy (see INTEGRATED MARKETING COMMUNICATION STRATEGY) focused on consumers rather than on members of the marketing channel in order to facilitate the flow of a good or service from a manufacturer to end-users (consumers). Conversely, a *push strategy* is defined as a promotion strategy focused on marketing intermediaries (wholesalers and retailers) rather than on consumers in order to facilitate the flow of a good or service from a manufacturer to consumers.

PUSH STRATEGY

A push strategy is a promotional strategy that “pushes” a product to the consumer through a distribution channel (intermediaries). This strategy focuses marketing activities on the use of aggressive selling (see SALES FORCE STRATEGY) and trade advertising (see INTEGRATED MARKETING COMMUNICATION STRATEGY) in order to convince intermediaries to carry, promote, and sell the product to consumers. In order to sell products to consumers, retailers often use advertising, point of purchase displays, and other promotions to convince consumers to buy the products. The advantage of this strategy is that it requires less manufacturer capital for advertising and promotional campaigns since awareness of a product is created by having it available for purchase in retail stores. Disadvantages of this strategy include inventory that retailers need to carry. In addition, a push strategy usually involves incentives to the distribution channel that increase marketing costs for the manufacturer. A push strategy is appropriate for products with low brand loyalty, where brand

choice is made in the retail store, and impulse purchases (Kotler, 2003). As an example of a push strategy, the Jamaican Tourist Board markets and promotes its island to and through travel and tour agencies. In return, these agencies market directly to consumers (Lamb, Hair, and McDaniel, 2006). This is considered a push strategy since promotional efforts are aimed at channel intermediaries (travel and tour agencies) instead of directly at consumers.

PULL STRATEGY

A pull strategy is a promotional strategy that focuses on building up consumers’ demand for a particular product. ADVERTISING MEDIA SELECTION AND PLANNING and direct-to-consumer promotions are used as a way to motivate consumers to search for and seek out a certain brand of product. Instead of retailers stocking products because of the incentives from a manufacturer, retailers purchase products from the manufacturer because of increasing demand from consumers. The manufacturer uses advertising, sampling, couponing, and other consumer promotions to encourage consumers to ask intermediaries for the product, thus encouraging the intermediaries to order the product. A pull strategy requires highly visible brands that can be developed through advertising campaigns, publicity, or word-of-mouth referral. The advantage of this strategy is that there is less retailer inventory since consumers’ demand drives the retailer to purchase from the manufacturer. The disadvantage of this strategy involves the high cost of advertising campaigns and publicity efforts to create a highly visible brand that will stimulate consumers’ demand in the marketplace. A pull strategy is appropriate for brands that have high levels of loyalty, when people understand the benefit differences between brands, and consumers can choose a brand prior to entering a retail store (Kotler, 2003). As an example of a pull strategy, a popular liquor company offered free on-site samples of the product coupled with extensive consumer advertising. These promotional efforts targeted to consumers created a demand for the product. Intermediaries such as wholesalers and retailers noticed consumer demand and consequently ordered the product to fulfill the requests of

2 push and pull marketing strategies

consumers. This is an example of a pull strategy since the promotional efforts were directly aimed at end-users instead of intermediaries.

PULL/PUSH COMBINATION STRATEGY

The type of strategy used depends on the product/market and product life cycle stage, and a variety of factors. For example, business-to-consumer companies tend to use pull strategies more than business-to-business companies (Kotler, 2003). Marketing strategies often rely on a combination of the two strategies in the promotion of a product. Few companies use a single strategy exclusively; however, one strategy may be emphasized over another. An example of a combined pull-push strategy can be seen in the pharmaceutical industry, where a push strategy is used by sending a sales force to promote drugs directly to physicians. This strategy is

supplemented with a pull strategy consisting of consumer-targeted advertising in magazines and on television (*see* MARKET SEGMENTATION AND TARGETING). Although pharmaceutical companies typically emphasize push strategies, pull strategies are becoming more common in this industry (Parker and Pettijohn, 2005).

sales force strategy

William L. Cron and David W. Cravens

INTRODUCTION

A major objective of the twenty-first century company and its sales force strategy is to deliver superior customer value. Sales organizations must design and implement sales force strategies that are consistent with the firm's business and marketing strategies and create a customer-focused sales organization. The competitive and rapidly changing global business environment places top priority on aligning an organization's strategies to satisfy the escalating requirements of customers and to increase business performance.

Our objective is to examine the nature and scope of sales force strategy in the creation and delivery of superior value to priority customers. We begin by defining sales force strategy and examining the hierarchical nature of business strategy. Next, we consider customer relationships including customer prioritization and generic types of customer relationships. Attention is then directed to sales force capabilities and their role in creating a competitive advantage. Finally, we discuss the management support system and sales force structure essential in supporting and enhancing sales force capabilities.

SALES FORCE STRATEGY IN PERSPECTIVE

In this section we define sales force strategy and discuss the hierarchical nature of business strategy.

Sales force strategy. Sales force strategy is defined here as *the set of strategic decisions that determine as the areas on which the sales force will focus its attention and the role of the sales force in creating customer value that is consistent with the overall strategy of the firm and/or business unit.* Several aspects of this definition should be noted. First, this definition of sales force strategy indicates that the focus of the sales force should be on creating high levels of customer value (see CUSTOMER ANALYSIS) that enhances customer satisfaction and contributes to high levels of profitability. This focus marries the goals of the

sales force with that of the overall organization in a market-driven organization. Second, the definition notes the hierarchical nature of sales force strategy, that is, a business strategy should drive a firm's MARKETING STRATEGY, which should guide the development of a firm's sales force strategy. Sales force strategy is conceived and executed within the context of an overall business strategy. This is to say that while a sales force's competencies and resources are considered when developing a firm's overall strategy, the sales force strategy in its totality is developed to best implement a firm's overall strategy. Third, sales force strategy is defined by a set of strategic decisions: customer prioritization, scope of customer relationship types, sales force capabilities portfolio, and a sales force structure and management support system to support these capabilities. The following sections further develop each of these sales force strategy elements.

Hierarchical context. As was mentioned earlier, the organizational context must be considered when examining sales force strategy. This includes considering the overall culture and basic philosophy of the organization. One aspect of culture that is of particular importance is the organization's basic orientation toward its markets. Sometimes referred to as a *market-driven strategy* (Cravens and Piercy, 2009), important characteristics include a firm's market orientation, customer focus, competitor focus, competitor intelligence, cross-functional coordination, and performance metrics (Cravens and Piercy, 2009).

Becoming market oriented involves getting the entire firm committed to the customer. The process requires the commitment and involvement of everyone in the company. The market-driven process begins with gaining an understanding of markets and customers by obtaining information on customers, competitors, and markets; analyzing the information through cross-functional involvement, deciding the strategic initiatives to pursue, and taking actions to deliver superior value to customers (Slater and Narver, 1994).

Achieving a customer focus is a demanding challenge. The organization must gain an understanding of customers' preferences and product

2 sales force strategy

use requirements coupled with using the capabilities and resources of everyone in the organization to meet buyers' value requirements.

Competitor intelligence plays a pivotal role in market-driven strategy (*see* COMPETITIVE ANALYSIS). The process involves far more than marketing research studies. Relevant competitors and technologies must be determined, their short-term strengths and weaknesses and long-term capabilities identified, and strategies for delivering superior customer value formulated and implemented (Slater and Narver, 1994). Too often, management defines the competitive arena on far too narrow a basis. Consider, for example, the negative impact of digital photography on Polaroid and Kodak.

Cross-functional coordination and collaboration are essential in delivering superior customer value. Many traditional multilevel and functionally specialized organizations experience major problems in achieving cross-functional cooperation. Marketing and sales are illustrative of the difficulty of breaking down functional walls. Importantly, cross-functional teamwork is essential in the customer value delivery process (*see* CROSS-FUNCTIONAL TEAM).

There is a positive relationship between market orientation and business performance. Research studies that were conducted in the United States and several other countries show very encouraging performance findings. Thus, the return from implementing market-driven strategy in various firms appears to be worth pursuing.

Another contextual aspect of the sales force strategy is the hierarchical nature of an organization's goals, objectives, and strategies. As shown in Figure 1, there are interactions among the organization levels including corporate, business unit, marketing, and sales force strategy. While our interest is on sales force strategy, it is relevant to recognize these strategy level relationships.

Corporate strategy. The organization's strategy includes determining the range and purpose of the firm, its objectives, and the strategy actions and resources required to accomplish the objectives. As shown in Figure 1, the relationships among the levels should be recognized. Corporate strategy should determine the strategic direction of a firm, deploy

Figure 1 Business strategy levels and relationships.

resources, and set limits on what opportunities the firm will pursue whereas business unit and marketing strategies provide important feedback on market knowledge (*see* MARKET/INDUSTRY STRUCTURE), opportunities, and threats. An essential part of corporate strategy is determining the corporate vision in terms of what the business is all about (Cravens and Piercy, 2009).

Business unit strategy. On the basis of the composition of the corporation in terms of markets and products (goods and services), many companies are organized into specific units called *business units* or *strategic business units* (Cravens and Piercy, 2009). Each unit will focus on a product area and satisfies a set of similar customer group requirements. The business unit performs all (or most) of the basic business functions. This organizational unit has an identifiable management team and is responsible for sales and financial performance. Typically, there is close coordination between the corporate and business unit levels.

Marketing strategy. The design and implementation of marketing strategy requires detailed knowledge of corporate and business unit strategy to assure that marketing strategy is consistent with corporate and business unit strategies (*see* MARKETING STRATEGY MODELS). The chief marketing executive is likely to be involved in higher level strategy formulation. It may be recalled that the management guru,

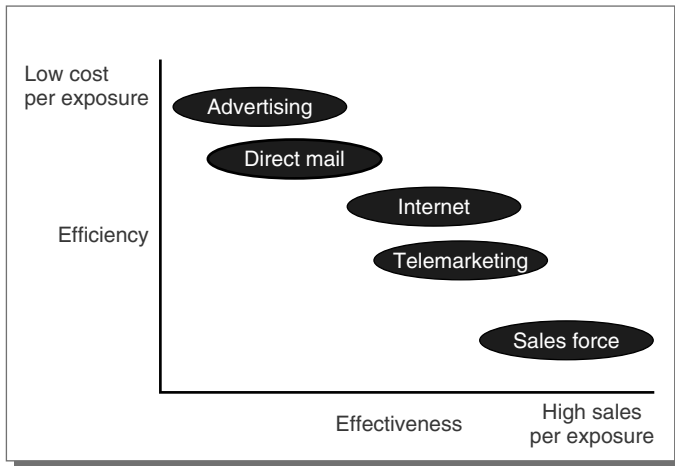

Figure 2 Comparing Go-To-Market alternatives.

Peter F. Drucker, defined marketing as a central dimension of the entire business.

Marketing strategy is concerned with developing a market vision for the organization, choosing market targets, setting objectives, and designing marketing program positioning strategies to respond to the value requirements of the customers in each target market (Cravens and Piercy, 2009).

For the sales force, a particularly important element of a firm's marketing strategy is its go-to-market strategy. A firm's go-to-market strategy defines the selling channel or combination of channels that can best execute a firm's marketing strategy (*see GO-TO-MARKET STRATEGY*). A wide array of selling channels exists today. In the past, firms typically chose a single channel to market, either their own direct sales organization or a group of distributors. Today, selecting the right selling channels is much more complicated. Companies reach out to their customers not only through direct sales and distributors but also through telemarketing, brokers, and manufacturer representatives, licensing arrangements, joint distributor agreements, dealers, new retail formats, and the Internet to name a few. Another factor that complicates the issue is the fact that companies sell through multiple channels to reach distinct customer segments and even to reach and service the same customers.

In general, companies are attempting to identify the best selling channels for executing their marketing strategy effectively and in the most cost-efficient way. Figure 2 compares several selling channels in terms of their effectiveness and efficiency. Note that a dedicated sales force is generally the least efficient (i.e., high cost per exposure), but the most effective (i.e., highest sales per exposure) means by which to connect to customers.

Sales force strategy. Marketing and sales force strategies require close coordination and collaboration. While sales force strategy is established within the context of a firm's marketing strategy, in the twenty-first century, the sales force plays an active role in planning many firm's marketing strategy, which requires close marketing and sales relationships.

Often, marketing and sales are organized as separate functions. Conflict may occur rather than collaboration between the functions, as indicated by many executive and academic thought leaders. This conflict is partially due to differences between the two functions in terms of what is considered critical and how a task is understood. For instance, marketing tends to be more product and long-term oriented, while sales is more customer and short-term oriented and possesses more granular market knowledge. Research has found that cooperation between

4 sales force strategy

marketing and sales is harmed to the degree that these departments differ along these orientation and knowledge dimensions. On the other hand, an organization's market performance is found to be enhanced when both a product and a customer orientation are represented in the organization (Homburg and Jensen, 2007). These results support the involvement of sales in planning marketing strategy and the need for cooperation between sales and marketing.

CUSTOMER RELATIONSHIPS

In this section we discuss the types of customer relationships that guide the process of customer value creation. This decision is related to and a function of how a firm prioritizes its customers, that is, which customers receive the bulk of the sales force's attention.

Prioritization of customers. This process involves segmentation and assigning priorities to customer segments. A firm's marketing strategy will include a statement as to the firm's target market based on its market segmentation approach. Market segmentation involves grouping customers so as to have (i) similar characteristics, (ii) similar needs, and (iii) a propensity to respond similarly to a marketing program. Target marketing involves prioritizing the segments on which the firm will focus its planning and concentrate its marketing resources (*see* MARKET SEGMENTATION AND TARGETING).

The sales force strategy further refines a firm's customer focus by developing even more precisely defined customer segments, sometimes referred to as *microsegments*, and driving the prioritization process down to the individual customer level. At this level, in prioritization of customers individual customer factors such as a customer's present sales volume, future sales and profit potential, strategy, values, depth of present relationship, and organization may be considered. The purpose of such precise customer prioritization is to maximize efficiency in allocating sales force resources by maximizing CUSTOMER SOLUTIONS. Customer prioritization guides the next decision, namely, which is the type customer relationship that a selling firm wishes to establish with its target customers? This is discussed next.

Types of customer relationships. Customer relationships based on investments made by the supplier and investments by the buyer range from *transactional*, *consultative*, and *enterprise* type buyer/seller relationships (Cron and DeCarlo, 2009). The selection of relationship strategy guides initiatives for acquiring, maintaining, and developing customers. The decision determines which customers can be profitability served since the level of seller investment increases in the span from transactional to enterprise type relationships. Large companies may establish two or even three types of relationships with different customer groups.

Transactional relationship. This relationship consists of a buyer's need for a product with acceptable characteristics and quality, competitively priced, and a buyer/seller purchasing process convenient for the buyer. A favorable transactional relationship typically involves a personal relationship between both parties when the purchasing process is ongoing.

A recent study concluded that 68% of all firms focus on a transactional relationship with at least some of their customers. The overarching reason for emphasizing transactional relationships in these situations is because the buyers are already quite knowledgeable about the product and the importance of the product itself in meeting the buyer's objectives.

Consultative relationship. This type of relationship calls for a more collaborative approach between the salesperson and the buyer. The customer wants and needs sales and support effort which delivers value in addition to the actual product. Sometimes referred to as *solutions selling*, customers generally engage in consultative relationships to solve a problem for which they are not certain of the solution. The challenge is convincing the buyer of the value of the consultative relationship. Customer value is created by the following methods:

- helping customers understand their problems and opportunities in a new or different way.
- helping customers develop better solutions to their problems than they would have discovered on their own.

- acting as the customer's advocate inside the supplier's organization, ensuring the timely allocation of resources to deliver customized or unique solutions to meet the customer's special needs (Cron and DeCarlo, 2009, 56).

The time demands for the salesperson are much greater for consultative compared to transactional relationships due to analysis of customer needs/requirements and coordinating assembly of the internal resources necessary to deliver customer value. Time investment in the relationship is substantial for both the seller and the buyer.

One or more of the following factors point to the value of a consultative relationship:

- the product or service can be differentiated from competitive alternatives;
- the product or service can be adapted or customized to the needs of the customer;
- the customer is not completely clear about how the product or service provides solutions or adds value;
- the delivery, installation, or use of the product or service requires coordinated support from the selling organization;
- the benefits of the product or service justify the relatively high cost of consultative relationships (Cron and DeCarlo, 2009, 56–57).

These conditions signal an opportunity to utilize consultative selling in creating superior customer value.

Enterprise relationship. A key driver of the use of enterprise relationships is the major trend of customer firms to significantly reduce the number of suppliers and develop enterprise type relationships with the remaining key suppliers. This relationship:

... is one in which the primary function is to leverage any and all corporate assets of the supplier in order to contribute to the customer's strategic success. In such a situation, both the product and the sales force are secondary, and the customer must be of strategic importance to the selling organization. (Cron and DeCarlo, 2009, 57).

Enterprise relationships may be designated by the supplier as key, strategic, major, national, or

global accounts. The intent of the relationship is positive value generation for both the customer and the key supplier. Interestingly, the customer is frequently the initiator of an enterprise type of relationship.

Enterprise relationships generally involve supplier teams drawn from different functional areas and organizational levels. The team may be managed by an executive. Supplier/customer trust is important because of joint decision making, exchange of proprietary information, and other collaborative interactions. "As the buyer-seller relationship becomes more sophisticated and complex, the sales force's role as the primary point of contact between customer and supplier often diminishes" (Cron and DeCarlo, 2009, 59). Many of the premier industrial firms in the United States such as GE, IBM, Du Pont, and Monsanto have established enterprise relationships with customers such as American Airlines, Ford, Miliken, Procter & Gamble, and the federal government.

Having decided on a customer relationship mix for its target markets, the next issue to be addressed is developing the sales force capabilities to support a selected type of customer relationship. Some fundamental sales force capabilities are described in the next section.

SALES FORCE CAPABILITIES

Having laid the groundwork by identifying the types of customer relationships the sales force is tasked with establishing, management is now in a position to address a core issue of sales force strategy, which is identifying the set of sales force capabilities necessary to successfully implement our customer relationship strategy. A capability refers to a firm's capacity to deploy and leverage resources to create customer value and a competitive advantage. Just as an individual may have the capability to play a violin or basketball, or speak German, so a sales force may be capable of landing new customers, sustaining and growing key customer relationships, and building deep trusting relationships.

There are two key aspects of capabilities to which attention should be devoted: resources and coordination/deployment of resources. Resources are the productive assets available to a firm (*see* MARKET-BASED ASSETS). There

are three principal types of resources: tangible (e.g., number of sales forces and sales offices), intangible (e.g., brand awareness and company equity), and human resources (e.g., sales force knowledge and attitude). It is important to recognize, however, that resources by themselves do not result in competitive advantage. Rather, resources must be leveraged to create a capability. It is capabilities that are the essence of superior performance.

Capabilities require the expertise of people to integrate with resources to establish routines, which are predictable patterns of activity, typically involving coordinated action by individuals (Barney, 1997). The focus of these routines is on creating value. So, an important capability for Honda Motor Company is its expertise in developing and manufacturing engines. This expertise has taken the firm into both automobiles and motorcycles, has been valuable to customers, and has created a competitive advantage for Honda.

Capabilities are hierarchical in nature. That is, broad organizational capabilities such as Honda's engine capability can be disaggregated into more specialist capabilities. Thus, we can think of the sales force as having certain capabilities such as its capability to acquire new customers, develop deep customer relationships, gain customer trust, and retain valuable customers.

Considered from this perspective, the sales force can be thought of as having routines for performing a set of important capabilities. Deciding on the nature and scope of these routines then is critical to developing sales force strategy. It is important to note, however, that the nature of these capabilities will be closely associated with the types of relationships the seller has with its customers. Table 1 describes how four sales force capabilities may differ depending on the nature of the seller-customer relationship. Note that trust is built in different ways in a transactional relationship, for instance, than it is in a consultative relationship. This is one of the reasons why companies may find it difficult to change from a transactionally oriented sales force to one that is consultative. Not only do new routines need to be learned and developed, but old ones need to be undone.

How successful a sales force will be in developing capabilities that will lead to superior

customer value and competitive advantage will depend on the organizational structure in which sales force capabilities are employed and management systems for supporting and enhancing the continuous development of these capabilities. This is where we direct our attention in the next section.

SALES FORCE STRUCTURE

Organizational structure should support the appropriate sales force activities associated with the sales force competencies. In other words, the structures should create stability and continuity of sales activities to support the development of routines. Importantly, the organizational design needs to facilitate coordination of sales force activities allocated to different members of the organization and different departments.

In this section, we discuss horizontal and vertical structures, team selling, and sales channel strategy.

Horizontal structure. A company may elect to outsource the sales function or use a company sales force. Alternative sales force structures include organizing by geography, type of product, type of customer, or selling function organizations (Cron and DeCarlo, 2009).

Outsourcing. Management may decide to utilize an independent organization to perform the sales function. The use of a manufacturer's representative is a popular option (Anderson and Trinkle, 2005). Representatives are independent businesses given exclusive contracts to perform the selling function within a specified geographic area. They take neither ownership nor physical possession of the products they sell and are always compensated by a commission on sales volume. The financial advantage of manufacturer representatives is in reduced capital requirements and favorable cash flow in that they are compensated only when sales are obtained.

Other outsourcing options involve contracting with value chain members to perform the sales function. For example, a producer may arrange for a distributor to provide sales coverage to retailers. The two key limitations of all outsourcing options is limited control by the firm utilizing the outsourcing option and higher

Table 1 Sales force capabilities and customer relationship type.

| <i>Sales Force Capabilities</i> | <i>Transactional Relationship</i> | <i>Consultative Relationship</i> | <i>Enterprise Relationship</i> |
|--|--|---|---|
| New customer acquisition | Prospecting is broadly targeted to general business categories. Appeal focuses on the product and/or price. | Prospecting is more targeted with referrals playing a larger role. The focus is on customer problems and solutions typically with some degree of customization of the seller's offering. | Prospecting is about identifying opportunities to collaborate with existing, strategic customers on mission-critical issues. The focus is on the opportunity to bring to bear supplier resources and capabilities on the customer's strategic issues and opportunities. |
| Customer relationship development | Building personal relationships with key customer personnel and growing the breadth of product and product lines that customers purchase. | Based on implementation of the solution and providing ongoing support and monitoring of evolving customer requirements. | Supplier leads deployment of the solution with customer oversight and is often responsible for running system following deployment and addressing any contingencies that might arise. |
| Customer trust building | The offering performs as promised. A deeper personal and professional relationship is developed between key participants and any problems are quickly and adequately resolved. | Sufficient enterprise-level value creation occurs based on cross-enterprise, cross-functional capabilities and commitments between supplier and customer. | The selling organization has the capability to provide insights into the customer's execution gaps, develop a joint vision of the relationship, and is willing to invest the resources necessary to execute and sustain the visions. |
| Customer retention | How well the product performs given its price and competitive offerings and the ability of the sales force to maintain key personal relationships. | The quality with which the selling organization provides support following deployment of the offering, which may include a tracking system of performance, sharing new insights, and providing cutting-edge upgrades. | Willingness to make changes to create value, sufficient potential to justify investment, cross-functional capability and commitment, and capability of organizational values. |

Table 2 Sales force structure specialization.

| <i>Organizational Structure</i> | <i>Advantages</i> | <i>Disadvantages</i> |
|---------------------------------|---|--|
| Geographic | Low cost No geographic overlap No customer overlap | Limited product line knowledge Limited customer knowledge Lack of management control over product or customer emphasis |
| Product | Product knowledge Control over product emphasis | Low geographic efficiency Customer duplication Geographic duplication |
| Customer | Deeper customer knowledge Control over customer emphasis | High cost Less product knowledge More geographic duplication Difficult coordination with product managers |
| Functional | Effectiveness in performing selling activities | Coordination Geographic duplication Customer duplication |

total costs compared to a dedicated sales force when sales exceed a certain threshold.

Specialization. A dedicated sales force may be specialized in a variety of ways. In addition to concern with the effectiveness with which sales capabilities are developed and supported, adaptability and efficiency are also important concerns when designing sales force structure. Sales organization adaptability is concerned with how quickly a company can react to product and market changes. Efficiency reflects the ease and speed with which key sales activities, for example, sales calls, proposals, product customization, can be performed.

Common structures for a specialized sales force include geographic, type of product, type of customer, or selling function organizations. Each type of specialization helps support critical sales force capabilities so as to meet the needs of customers and to excel against direct competitors. While each type of sales force specialization has its advantages, there are also disadvantages to each type of organization which management will attempt to minimize. The advantages and disadvantages of each type of sales force organization are listed in Table 2. There has been a trend in recent years, however, toward customer specialization and away from a purely geographic organization.

Team selling. The use of sales teams requires attention to the design of the team selling structure (Cron and DeCarlo, 2009). Teams may be used with large and more attractive customers owing to the financial cost associated with team selling. They are normally used with enterprise relationships and may be appropriate in certain consultative relationships. A team may comprise people from several functions and a team leader. These designs include challenges in coordination and collaboration but may offer sufficient advantages to overcome the limitations.

Vertical structure. The vertical structure of the sales organization consists of the number of levels of management between the chief sales executive and salespeople. The greater the number of levels, the fewer people each manager supervises. Multiple management levels were considered essential in the past to facilitate communications and interactions up and down the organization. Significant advances in information technology have substantially improved communications between and across levels. Nonetheless, in sales the range of span of control is quite large across companies with as few as 3 salespeople per manager to as many as 30. The most common range is probably between 7 and 12.

The issues of number of management levels and span of control are important because they directly affect sales force costs and revenues.

Determining the number of management levels and number of people supervised may depend on relevant situation-specific factors (e.g., product support requirements and type of customer relationship). In general, a flat organization and a wider span of control are appropriate when the managerial task is less time consuming. Factors that increase the amount of time that a manager needs to spend with individual salespeople include:

1. wide geographic dispersion of salespeople;
2. many inexperienced salespeople; and
3. extensive coordination required across salespeople or with others in the organization (Zoltners, Sinha, and Lorimer, 2004, 168).

Sales territory design. An important aspect of designing an effective sales organization is the design of sales territories. Customers have a level of activity and coverage that is needed to properly service them, while salespeople have an activity capacity. Sales territories consist of the customers located in a specified geographic area that are assigned to an individual salesperson. While territories are often referenced in geographic terms, the defining element of a territory is the set of customers in the geographical area.

A properly aligned sales territory is one in which customers receive the appropriate level of sales force attention and the workload is balanced across salespeople. There appears to be a great opportunity for improvement with respect to proper territory alignment. A study of over 4800 sales territories found that well over half of the territories were not the right size. Approximately 25% of the territories were too large to be effectively covered, while 31% were too small to keep a salesperson sufficiently busy with productive work (Zoltners, Sinha, and Lorimer, 2004, 274).

Sales territory alignment is an ongoing course of business requiring frequent minor adjustments, but major realignments are also needed every few years at many companies. Conditions that create major territory realignments include when a company changes its type of customer relationship focus, significantly increases/decreases the size of its sales force, creating new products, and there are significant

mergers and acquisitions. Experts suggest that companies audit their territory alignments annually.

MANAGEMENT SUPPORT SYSTEM

The sales organization's management support system plays a vital role in the performance of the organization through its impact on sales force capabilities. In this section, we discuss management control processes, metrics alignment, the motivation system, and talent development.

Management control processes. Behavior-based and outcome-based sales force management control systems were proposed over 20 years ago (Anderson and Oliver, 1987). Behavior-based management control consists of specific sales management activities (monitoring, directing, evaluating, and rewarding salespeople), and the extent to which managers perform these activities. Compensation consists of relatively high percentages of fixed salaries for salespeople. Outcome-based control utilizes relatively high levels of incentive compensation for salespeople and relatively limited sales manager control activities.

Behavior control is focused on salesperson selling behavior whereas outcome control is more concerned with salesperson results. Under outcome control, salespeople have very limited interaction with sales managers during their sales processes. Minimal monitoring and manager direction occur. Behavior control is primarily concerned with the processes salespeople use to obtain sales results.

There is substantial research support for a positive impact of behavior control on salesperson performance, which in turn displays a positive relationship with sales unit effectiveness. Salesperson performance comprises behavior and outcome performance. Behavior performance has been found to have a strong positive relationship with salesperson outcome performance, which has a positive impact on sales unit effectiveness.

The intent is not to suggest that behavior control is a favorable management process and outcome control has a negative impact on salesperson performance and sales unit effectiveness. Instead, behavior control appears more

appropriate for nontransaction type buyer/seller relationships.

Metrics alignment. An important aspect of sales force strategy is tracking how well the strategy is performing. Marketing and sales force metrics are of strong interest in many companies driven by concerns as to the measurement of performance and relating it to business performance. Metrics has been assigned a top priority research issue by the Marketing Science Institute (MSI) (see MARKETING METRICS). MSI is a not-for-profit research organization funded by corporate members who set research priorities. A key issue is developing measures for marketing and sales that are related to business performance.

Illustrative metrics include tracking position relative to competition, CUSTOMER LIFETIME VALUE (CLV), strategy effectiveness, and financial performance. Normally, multiple measures are recommended. Sales organization metrics should be compatible to those used by the business and the marketing function. Sales metrics are needed but should be extended to include areas such as account profitability and contribution to profit.

Sales managers need to develop knowledge as to what strategy actions lead to improved sales productivity. Sales management behavior control is an example since research findings indicate a positive relationship with sales organization effectiveness. Effectiveness has been measured based on sales, market share, profitability, and customer satisfaction.

Motivation system. Motivating salespeople is a continuing challenge for sales organizations. While motivation is in part self-generated, development of an internal organizational motivation system is an essential aspect of sales force strategy. We know that motivation is a very relevant influence on job performance (see MOTIVATION RESEARCH). The starting point is gaining an understanding of the factors that influence a person's motivation.

Accumulated knowledge on motivation points to the interplay between three factors affecting the amount of effort someone will put into an activity: (i) the relationship between effort and performance, referred to as *expectancy*; (ii) the

relationship between performance and rewards, called *instrumentality*; and (3) the importance of receiving more of a certain reward, known as *valence* (Cron and DeCarlo, 2009). Combined, these three factors provide a framework for managers to understand the internal process by which people are motivated to put forth extra effort.

There are several sales management actions that may have a positive impact on motivation of sales personnel. These actions include helping salespeople set challenging yet achievable goals; rehearsing desired behaviors through one-on-one coaching, setting fair and challenging quotas, incentive programs, and recognition programs (Cron and DeCarlo, 2009, 249–251).

Talent development. It is generally agreed that talent development is the most important dimension of sales management. Talent development focuses on the issues of having the right people with the right values, skills, and capabilities. It encompasses recruiting, training, coaching, and culture development. Underlying successful execution of each sales force capability is the appropriate level of sales force knowledge, attitude, and values.

Hiring is a critical activity because it affects company results, management effectiveness, and company culture. A report by the Harvard Business School estimates that a bad hiring decision can cost a company three times the salesperson's annual compensation, including expenses, training costs, benefits, and incentive pay. Likewise, new recruits bring their own values to the company. Successful people can become heroes for the company and successful "war stories" become the legends of the company.

Companies can successfully take different approaches to talent development. Selling organizations such as Procter & Gamble, Johnson & Johnson, and Xerox primarily hire recent college graduates for the sales positions and train them thoroughly to be successful. Training programs are considered a corporate capability that generates a competitive advantage for these companies. In contrast, other companies hire only people with sales experience. They expect the new hires to integrate quickly and contribute to the selling effort. A fundamental question that

management should ask itself is which salesperson characteristics can be developed through training and which are innate? It should be borne in mind that only skills and knowledge can be trained.

CONCLUSION

We have defined and examined the various dimensions of sales force strategy, which consists of a set of strategic decisions that determine who the sales force will sell to and the role of the sales force in creating customer value that is consistent with the overall strategy of the firm and/or business unit. At the center of the strategy process is the delivery of superior customer value to targeted customers. The past role of the sales force has changed from primarily implementing strategy to becoming an active participant in marketing strategy development.

Sales force strategy is linked to corporate business units, and marketing strategies in an interrelated hierarchy of relationships. Marketing and sales force strategies require close coordination and collaboration. Prioritization of customers is a key joint effort which is intended to result in determining the types of customer relationships pursued by the firm. The options include *transactional*, *consultative*, and *enterprise* relationships. The determination of the relationship strategy (or strategy combination) provides the guidelines for actions in acquiring, maintaining, and developing customers.

Sales force strategy requires developing sales force capabilities to support each type of strategic relationship. These include new customer acquisitions, customer relationship development, customer trust building, and customer retention. Sales force capabilities may vary depending on the nature and requirements of the seller-customer relationship. These demands make it difficult for a company to change from a transactional oriented sales force to one that is consultative.

Developing the necessary capabilities to achieve superior customer value and competitive advantage is very dependent on selecting the appropriate organizational structure in which sales force capabilities are employed and management systems for supporting and enhancing the continuous development

of these capabilities. Horizontal structure choices include possible outsourcing, extent of specialization (geographic, type of product, type of customer, and/or selling function), and use of team selling. Vertical structure decisions need to address the number of levels and span of control of sales management and sales territory design.

The management support system consists of choices concerning control processes, metrics alignment, the motivation system, and talent development. Control focuses on the extent of behavior versus outcome control. Metrics choices are essential in tracking how well the strategy is performing. The motivation system determines which management actions will be used to create a positive impact on motivation of sales personnel. Talent development focuses on the issues and choices of having the right people with the right values, skills, and capabilities as members of the sales force.

A successful sales force strategy requires appropriate choices concerning the various customer relationship, sales force capabilities, organizational structure, and management support system decisions. These strategy dimensions are closely related and require careful integration. The end result should provide a successful superior customer delivery system.

services marketing strategy

Valarie A. Zeithaml, Mary Jo Bitner, and
Dwayne D. Gremler

Services marketing strategy focuses on delivering processes, experiences, and intangibles to customers rather than physical goods and transactions. It involves integrating a focus on the customer throughout the firm and across all functions. All company functions – marketing, selling, human resources, operations, and R&D – must work together to create effective services marketing strategy. Rather than the traditional goods marketing focus on transactions and exchange, services marketing strategy is centered on the customer, usage, and relationships (Vargo and Lusch, 2004a).

Services, which can be defined as *deeds, processes, and performances*, fall into several categories. Many services, such as hotels, transportation, and health care, are offerings in and of themselves and are the primary revenue-producing activities of the firms. Another category of service is customer service, which includes the service provided in support of a company's core products. Typically, customer service does not directly produce revenue but rather addresses customer requests, questions, and complaints, besides providing answers and solutions. Service can also be a value-add for manufactured products – many companies provide training, installation, and repair services for the goods they produce – often for a fee. Finally, many services are derived from or are provided by manufactured products such as cell phones, computers, software, and mobile phones. In early writings on services, scholars distinguished services from goods by noting that they were intangible, perishable, variable, and that the producer and consumer were inseparable. Recently, it has been suggested that these distinctive characteristics should not be viewed as unique to services but that they are also relevant to goods, that “all products are services,” and that “economic exchange is fundamentally about service provision” (Vargo and Lusch, 2004b). Although this view is rather abstract, it does suggest that all types of organizations can gain valuable insights from services marketing frameworks, tools, and strategies.

The four Ps of marketing (product, price, promotion, and place) are only partially adequate to conduct effective services marketing strategy. Three additional Ps – *people*, *process*, and *physical evidence* – are also needed. Because services are usually produced and consumed simultaneously, customers are often present in the firm's factory, interact directly with the firm's personnel, and are actually part of the service production process. Therefore, all human actors (the P corresponding to people) play a part in service delivery and thus influence the customer's perceptions. The firm's personnel, the customer, and other customers in the service environment each provide cues to the customer regarding the nature of the service itself. Employee dress, personal appearance, attitudes, and behaviors all influence the customer perceptions of the service. Physical evidence pertains to the environment in which the service is delivered; all tangible components that facilitate performance or communication of the service also affect services marketing. This includes all the tangible representations of the service such as brochures, letterheads, business cards, report formats, signage, and equipment, and the *servicescape*, the physical facility where the service is offered. This P (physical evidence) is needed for services because customers often have little on which to judge the actual quality of an intangible offering and thus will rely on any tangible components of the service offering. Finally, process – including the operating systems, procedures, mechanisms, and flow of activities by which the service is delivered – is an element of the services marketing mix. This P (process) addresses how the service is delivered, which, in many cases, may be perceived by customers to be as important as the outcome of the service. In the discussion that follows, the impact of these additional three Ps in services marketing strategy will be obvious.

GAPS MODEL OF SERVICE QUALITY

Executives of services organizations have long struggled with how to approach service design and delivery in an organized manner. The dominant approach to viewing the delivery of service quality in a structured and integrated way is called the *gaps model of service quality*

2 services marketing strategy

(Parasuraman, Zeithaml, and Berry, 1985). The gaps model positions the key concepts, strategies, and decisions in delivering quality service in a manner that begins with the customer and builds the organization's tasks around what is needed to close the gap between customer expectations and perceptions. The gaps model provides a comprehensive and integrating framework for delivering service excellence and customer-driven service innovation.

The model is particularly relevant in service strategy because it captures the cross-functionality inherent in service management. Although the authors are marketing academics and their original publications appeared in marketing journals, their work has been widely cited and used across academic disciplines and implemented in different functions within organizations. The model draws heavily from logic, theories, and strategies in operations, human resources, marketing, and increasingly from information systems.

The model, illustrated in Figure 1, is anchored on the customer and integrates customer focus throughout all gaps within the model. As depicted in the model, a firm's primary goal should be to meet or exceed customer expectations, and strategies used to achieve that objective (whether operations, human resource, or technology-based) are all focused on the customer. Every gap and every strategy used to close the gaps in the model retains a focus on the customer at its core.

The central focus of the model is the *customer gap* – the difference between customer expectations of what will be delivered and perceptions of the service as it is actually delivered. The other four gaps in the model are known as the *provider gaps* and each represents a potential cause behind a firm's failure to meet customer expectations. Closing the customer gap – delivering quality service – at the top of the model is a complex undertaking involving many different organizational and employee skills and tasks. These tasks can be sorted into four other gaps – the provider gaps – each of which needs to be closed in order to close the customer gap.

The following four provider gaps, shown under the horizontal line in Figure 1, are the underlying causes behind the customer gap:

Gap 1: The listening gap

Gap 2: The service design and standards gap

Gap 3: The performance gap

Gap 4: The communication gap.

At its most basic level, the logic of the model suggests that the customer gap is a function of any one or all of the four provider gaps. Early publications of the gaps model enumerated the complex reasons that cause each of these provider gaps. Later publications and a leading services marketing textbook (Zeithaml, Bitner, and Gremler, 2009) have further elaborated on the gaps by delineating specific strategies for closing each of them. We will expand briefly on key strategies used to close each of the gaps.

THE CUSTOMER GAP

The customer gap is the heart of the gaps model. It represents the difference between customer expectations and perceptions of service performance. The model suggests that closing this gap by matching or exceeding customer expectations will result in the achievement of service quality from the customer's perspective. In the years since the introduction of the model, there has been significant focus on both customer expectations and perceptions in terms of conceptualizing these constructs, developing measures for them, and studying their effects.

A prominent focus of both academic and practical research has involved identifying the dimensions of service quality. Considerable exploratory and empirical work resulted in the identification of five dimensions:

1. *Assurance:* Knowledge and courtesy of employees and their ability to inspire trust and confidence.
2. *Empathy:* Caring, individualized attention the firm provides its customers.
3. *Reliability:* Ability to perform the promised service dependably and accurately.
4. *Responsiveness:* Willingness to help customers and provide prompt service.
5. *Tangibles:* Appearance of physical facilities, equipment, personnel, and communication materials.

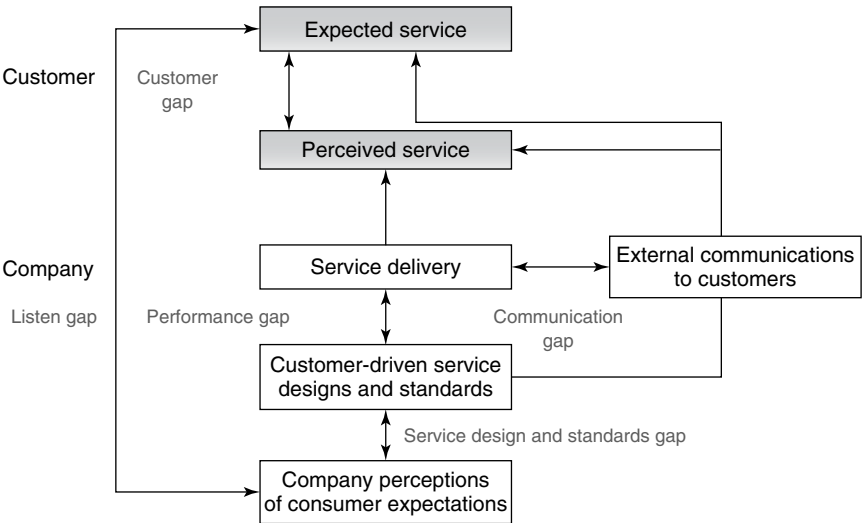

Figure 1 Gaps model of service quality.

The five dimensions of service quality have been captured in a questionnaire called *SERVQUAL*, consisting of a total of 21 items measuring these dimensions. The *SERVQUAL* measure has been applied in and adapted to many industry settings. Related streams of research have developed in parallel to study service encounters, customer satisfaction, customer loyalty, and their relationships with service quality. None of these now-prominent streams of research existed prior to the 1980s, and all continue to spawn research today.

GAP 1 – THE LISTENING GAP

Provider gap 1, the *listening gap*, is the difference between customer expectations of service and company understanding of those expectations. A primary cause in many firms for not meeting customers' expectations – that is, the customer gap – is that the firm lacks accurate understanding of exactly what those expectations are. Many reasons exist for managers not being aware of what customers expect: They may not interact directly with customers, they may be unwilling to ask about expectations, or they may be unprepared to address them. Closing the listening gap requires that management or empowered employees acquire accurate information about customers' expectations. Customer expectations

must be assessed accurately before new services are developed, and they must be tracked after the services are introduced.

Figure 2 lists the three key strategies for closing the listening gap. Each of these strategies is backed by research and practical applications. The first strategy is to listen to customers in multiple ways through customer research and employee upward communication. Such research includes the full range of traditional marketing research methods such as surveys, focus groups, and complaint handling. There have also been research methods uniquely useful in service situations such as *SERVQUAL* surveys, mystery shopping, and critical incidents analysis. A distinguishing factor between marketing research on goods and services is that services research must capture human performance. Whereas goods research can evaluate goods independent of the individuals who create them, service is often created in the interaction between customers and contact personnel. The behavior of personnel can be highly variable across individuals as well as with employees from day to day, so constant monitoring must occur. For that reason, additional techniques are needed to assess and feedback information about the performance of individuals. *Mystery shopping* – hiring people

Figure 2 Strategies for closing the listening gap.

to pose as customers to evaluate performance – is typically used in restaurants and other retail service settings. *Critical incidents research*, in which a customer recalls and discusses both satisfying and unsatisfying experiences with a service provider and its employees, is particularly useful in examining and improving service encounters. Another marketing research approach that is particularly useful in service firms is the *trailer call*, a short survey that follows (“trails”) a service event or encounter. The trailer call offers quick feedback on employees and also allows a company to fix its processes in a timely fashion.

The second strategy that closes provider gap 1 is to focus on building relationships by understanding and meeting customer needs over time. In firms where customers and companies have interpersonal contact, this can involve many different strategies: learning customers’ names, their businesses, their industries, and their histories with the firm. Even in direct marketing or online situations, a firm can develop a virtual relationship with customers by learning their preferences and history. The stronger the firm’s relationship with its customers, the better is the firm’s ability to listen to customers (and thus close the listening gap).

The final key factor associated with provider gap 1 is lack of service recovery, or a failure to understand and act on what customers expect when there is a service failure. Even the best companies, with the best of intentions and clear understanding of their customers’ expectations, sometimes fail. It is critical for an organization to understand the importance of service recovery – why people complain, what they expect when they complain, and how to develop effective service recovery strategies for dealing with inevitable service failures. Such strategies

might involve a well-defined complaint-handling procedure and an emphasis on empowering employees to react on the spot, in real time, to fix the failure; at other times, it involves a service guarantee or ways to compensate the customer for the unfulfilled promise. Firms that learn from their failures – which often result from not fully understanding their customers’ expectations – can reduce or eliminate the listening gap.

GAP 2 – THE DESIGN AND STANDARDS GAP

Closing gap 1 through research and effective management of customer relationships is necessary, but not sufficient, for achieving service excellence. Even when a company has a thorough and ongoing understanding of its customers’ expectations, it is still very possible, in fact, quite easy, to fail to deliver quality service. Focusing on gap 2, the design and standards gap, is the next step toward ensuring against such failure. This gap is concerned with translating customer expectations into actual service designs and developing standards to measure service operations against customer expectations.

Figure 3 summarizes several key strategies for closing gap 2. The first strategy is to employ well-defined new-service development and innovation practices for designing services. Some have referred to this as *formalization* of a “services R&D” practice. While standardized new-product development processes and R&D are common in technology and manufacturing, they are still quite rare in services (for a major exception, we note the investment of the IBM Corporation in service innovation research through its global research labs). A formalized process typically involves a series of steps beginning with strategy formulation and idea

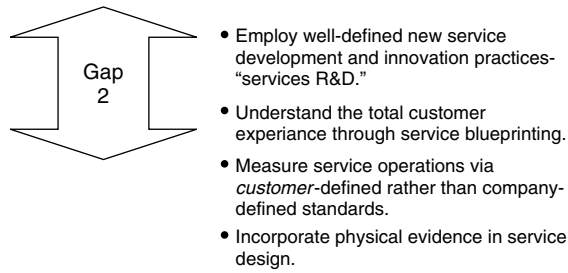

Figure 3 Strategies for closing the design and standards gap.

generation and ending with full-scale implementation. Because of the nature of services (their process orientation, intangibility, cocreation by customers), it is more challenging to engage in these typical steps that are so well established in other industries. However, it is clear that following a well-defined process, engaging customers along the way, and carefully planning and prototyping the complexities of service implementation are all essential in ensuring service designs that meet customer expectations. Building prototypes of services and planning for eventual full-scale implementation again means that operations, marketing, and, in many cases, human resource functions must work together.

A second strategy for closing gap 2 relates to understanding the total customer experience and designing all elements of that experience in ways that meet or exceed customer expectations. This involves considering everything that occurs from the moment the customer engages the service through the entire length of the service experience. Common elements of the service experience that need to be designed include customer-facing processes, the physical space where the service is delivered, and the interactions between service employees and customers. Viewing these operational elements from the customer's perspective and designing them to be consistent with expectations, or to reinforce a desired service image, are critical to closing gap 2. Because of the special challenges inherent in designing services, techniques such as *service blueprinting* have evolved to aid in the design process (Zeithaml, Bitner, and Gremler, 2009). The purpose of a service blueprint is to make a complex and intangible service concrete through its visual depiction of all of the steps, actors,

processes, and physical evidence of the service. The key feature of service blueprints is their focus on the customer – the customer's experience is documented before any of the internal processes are determined.

A third strategy for closing gap 2 involves measuring service operations via *customer-defined standards*. These are standards set to correspond to customer expectations rather than to firm-focused goals. The quality of service delivered by customer-contact personnel is critically influenced by the standards against which they are evaluated and compensated. Standards signal to contact personnel what the management priorities are and which types of performance really count. When service standards are absent or when the standards in place do not reflect customers' expectations, quality of service as perceived by customers is likely to suffer. Customer-defined standards can either take the form of operational (hard) or perceptual (soft) standards.

The final strategy that closes gap 2 involves the use of physical evidence in service design and in meeting customer expectations. This includes everything tangible in the service-delivery process, such as business cards, reports, signage, Internet presence, equipment, and facilities used to deliver the service. The servicescape, the physical setting where the service is delivered, is a particular focus of physical evidence and is critical in industries such as restaurants and hotels to communicate about the service and make the entire experience pleasurable. In these cases, the servicescape plays a variety of roles, from serving as a visual metaphor for what the company stands for to actually facilitating the activities of both consumers and employees.

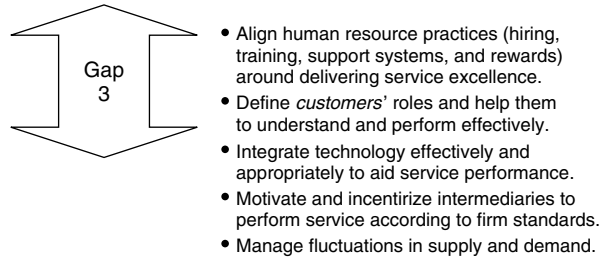

Figure 4 Strategies for closing the service performance gap.

Given the importance of physical evidence and its potentially powerful influence on both customers and employees, it is important for firms to think strategically about the design and management of the tangible evidence of service.

To accomplish the type of customer-focused service design described above means that marketing and operations functions within the firm must at least share information, and, in the best case, actually collaborate in designing the service and setting standards for its delivery. Because of the interpersonal nature of many services it is critical to design and plan for the human element as well; thus, effective service design and customer-defined standards will reflect collaboration with the human resource function in the organization. These types of cross-functional collaborations are not as essential in goods marketing where process, people, and physical evidence (the new-services marketing mix elements) are not as critical in defining the product.

GAP 3 – THE PERFORMANCE GAP

Although a company may have closed both the listening gap and the service design and standards gap, it may still fall short of providing service that meets customers' expectations if it is unable to deliver service in the way the service was designed. Gap 3, the service performance gap, must also be closed to make sure there is no discrepancy between customer-driven service design and standards and actual service delivery. Even when guidelines exist for performing service well and treating customers correctly, high-quality service performance is not a certainty. Standards must be backed by appropriate resources (people, systems, and

technology) and also must be enforced to be effective – that is, employees must be measured and compensated on the basis of performance along those standards. Thus, even when standards accurately reflect customers' expectations, if the company fails to provide support for those standards – if it does not facilitate, encourage, and require their achievement – standards do no good. When the level of service delivery falls short of the standards, it falls short of what customers expect as well. Narrowing gap 3 by ensuring that all the resources needed to achieve the standards are in place reduces the customer gap.

The key strategies for closing gap 3 are depicted in Figure 4. The first strategy is to align the firm's human resource strategies around delivering service excellence. In particular, in order to deliver service as it was designed a firm needs to ensure that employees are willing and able to deliver quality services and that they are motivated to perform in customer-oriented, service-minded ways. In creating such a workforce, an organization must hire the right people, develop those people to deliver service quality, and retain the best people. To effectively deliver service quality, considerable attention should also be focused on recruiting and hiring the right service personnel. Service employees need two complementary capacities: *service competencies* – the skills and knowledge necessary to do the job – and *service inclination* – an interest in doing service-related work. Once the right people are in place, to provide quality service they need to be developed through ongoing training in the necessary technical skills and interactive skills. An organization that hires the right people and trains and develops them to deliver service quality must also work to retain them. If a

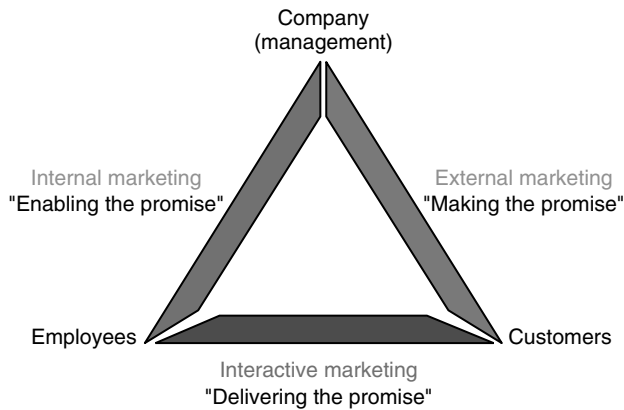

Figure 5 The services marketing triangle.

company wants the strongest service performers to stay with the organization, it must reward and promote them. Organizations use a variety of rewards to retain the best employees; traditional approaches such as higher pay, promotions, and one-time monetary awards or prizes are often linked to service performance.

Services marketing is about promises made and promises kept to customers. A strategic framework known as the *services triangle* (Figure 5) visually reinforces the importance of people in the ability of firms to keep their promises and succeed in building customer relationships (Bitner, 1995; Kotler, 1994; Grönroos, 2007).

The triangle shows the three interlinked groups that work together to develop, promote, and deliver services. These key players are labeled on the points of the triangle: the company (or SBU (small business unit) or department or “management”), the customers, and the providers. Providers can be the firm’s employees, subcontractors, or outsourced entities who actually deliver the company’s services. Between these three points on the triangle, three types of marketing must be successfully carried out for a service to succeed: external marketing, interactive marketing, and internal marketing.

On the right side of the triangle are the *external-marketing* efforts that the firm engages in to set up its customers’ expectations and make promises to customers regarding what is to be

delivered. Anything or anyone that communicates to the customer before service delivery can be viewed as part of this external-marketing function. But external marketing is just the beginning for services marketers: promises made must be kept. On the bottom of the triangle is what has been termed *interactive marketing* or *real-time marketing*. This is where promises are kept or broken by the firm’s employees, subcontractors, or agents. People are critical at this juncture. If promises are not kept, customers become dissatisfied and eventually leave. The left side of the triangle suggests the critical role played by *internal marketing*. Management engages in these activities to aid the providers in their ability to deliver on the service promise: recruiting, training, motivating, rewarding, and providing equipment and technology. Unless service employees are able and willing to deliver on the promises made, the firm will not be successful, and the services triangle will collapse.

All three sides of the triangle are essential to complete the whole, and the sides of the triangle should be aligned – that is, what is promised through external marketing should be the same as what is delivered; and the enabling activities inside the organization should be aligned with what is expected of service providers.

For many services, customers are participants in service production and cocreators of value and, therefore, play a key role in the service-delivery process – that is, customers themselves can influence whether the service

meets customer-defined specifications and can potentially contribute to the widening of gap 3. Therefore, a second strategy for closing the performance gap is to define customers' roles and assist them in understanding and performing their roles effectively. Sometimes customers widen gap 3 because they lack understanding of their roles and exactly what they are to do in a given situation or because they are unwilling or unable to perform for some reason. To reduce this gap the organization needs to clearly define and communicate what the customer's role entails – in essence, the customer's job description. Once the customer's role is clearly defined, the firm needs to help facilitate that role. In a sense, the customer is a "partial employee" of the organization, and strategies for managing customer behavior in service production and delivery can mimic, to some degree, the efforts aimed at service employees discussed in the previous paragraph.

A third strategy for closing gap 3 involves integrating technology effectively and appropriately to aid service performance. For service workers (and customers) to be efficient and effective in performing their jobs, technology that facilitates their efforts is often required. Technology can help employees to be more effective and efficient in serving customers. Technology can also help customers become more educated and involved in cocreating service. In some cases, technology can serve as a substitute for employees, and actually deliver the service to the customer without any need for human interaction. These types of services – called *self-service technologies* – are prevalent today across industries.

A fourth difficulty associated with provider gap 3 involves the challenge in delivering service through such intermediaries as retailers, franchisees, agents, brokers, subcontractors, and outsourcers. Because quality in service often occurs in the human interaction between customers and service providers, control over the service encounter by the company is crucial, yet it rarely is fully possible. Most service (and many manufacturing) companies face an even more formidable task: attaining service excellence and consistency in the presence of intermediaries who represent them and interact with their customers yet are not under their

direct control. Franchisers of services depend on their franchisees to execute service delivery as they have specified it. And it is in the execution by the franchisee that the customer evaluates the service quality of the company. With franchises and other types of intermediaries, someone other than the producer is responsible for the fulfillment of quality service. This issue has become particularly relevant as firms increase the outsourcing of their customer support to other countries; concerns about language, quality control, and consistency of performance are the ultimate trade-offs for lower costs. Because firms often provide service through intermediaries, they must develop ways to either control or motivate these intermediaries to meet company goals and perform as well as their own employees.

A final issue in provider gap 3 is the need in service firms to synchronize demand and capacity. Because services are perishable and cannot be inventoried, service companies frequently face situations of over demand or under demand. Lacking inventories to handle over demand, companies lose sales when capacity is inadequate to handle customer needs. On the other hand, capacity is frequently underutilized in service companies during slow periods. Most companies rely on operations strategies such as cross training or varying the size of the employee pool to synchronize supply and demand. Marketing strategies for managing demand – such as price changes, advertising, promotion, and alternative service offerings – can supplement approaches for managing supply.

GAP 4 – THE COMMUNICATION GAP

Even when a firm has done everything suggested by the other three gaps to ensure service quality, there can still be a failure to meet customer expectations if communications about the service do not match with what is delivered. Thus, the final provider gap that must be closed is the *communication gap*, or gap 4. This gap focuses on the difference between service delivery and what is communicated externally to customers through advertising, pricing, and other forms of communications.

Figure 6 captures several key strategies for closing gap 4. The first strategy revolves around

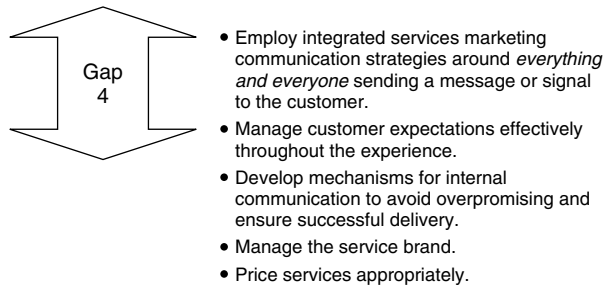

Figure 6 Strategies for closing the communication gap.

integrated services marketing communication that ensures that everything and everyone sending messages or signals about the service does so in a manner that is consistent with what customers expect and what is actually delivered. The challenge with this strategy is that there are a myriad of communication channels and modes that send messages to customers – more today than ever before – including traditional websites, personal sales, direct mail, print media, blogs, virtual communities, mobile advertising, and television. Beyond these types of channels, which are also available to goods-producing firms, service customers receive additional communication from servicescapes, customer service representatives, and everyday service encounters with company employees. Ensuring that all of these channels communicate effectively and consistently is a daunting task, yet one that is essential to an integrated communication strategy. Unfortunately, the people within companies that deal with these different communication vehicles are not always located in the same department, leading to disparate, conflicting messages.

A second key strategy for closing the communication gap is to manage customer expectations effectively throughout the service experience. Many services (e.g., many business-to-business services and consumer membership services) take place over an extended time frame that might mean a few hours, days, weeks, or even years. These extended service experiences often change over time, varying from the original service promise as a result of business realities (for either the provider or the customer) that change the nature of the service, customer needs that change over time, and financial pressures

that may cause increases in pricing or adjustments to the service contract. Thus, communications to the customer must also evolve through time to ensure that expectations and service performance match. This might mean managing customer expectations relative to new business realities, often in the form of managing expectations downward when a service previously provided is discontinued or when prices for similar services must be increased.

A third strategy for closing gap 4 is to develop mechanisms for internal communication so that the customer hears consistent messages before the sale and during service delivery. A common cause for the communications gap is overpromising on the part of customer-contact employees, salespeople, and marketing communications. While a certain amount of promotion is needed in many cases to gain a sale, excessive promotional activity can be detrimental when it exceeds the ability of the delivery organization to keep the promises made. Customers gained in the short term through excessive promises can be lost just as quickly through a failure to deliver. A number of internal communication strategies can help avoid the latter problem. These strategies including effective vertical communication that keeps employees informed of corporate plans and marketing messages so that they communicate accurately to consumers. Selling the brand inside the company also helps employees to see its value and to be realistic about what can and should be promised to customers. Horizontal communication across marketing, operations, and service design teams can also help align promises with service-delivery capabilities.

A fourth strategy to close the communications gap is to create a strong brand image for

the service. A brand image – reinforced by brand characters, slogans, logos, and similar images – serves to unify perceptions of the brand. Service organizations such as Chick-fil-a, with its ubiquitous cow, or McDonalds, with its golden arches, have successfully created brand images over time that reduce the communications gap.

A fifth issue in provider gap 4 is associated with the pricing of services. In packaged goods (and even in durable goods), customers possess enough price knowledge before purchase to be able to judge whether a price is fair or in line with competition. With services, customers often have no internal reference points for prices before purchase and consumption. For this reason, determining the value of a service to customers, called *demand-oriented pricing*, can be complicated. Further, pricing strategies such as discounting, “everyday low prices,” and couponing obviously need to be different in service cases in which the customer has no initial sense of prices. Even cost-based techniques for developing prices for services are more complicated than those for pricing tangible goods, largely because the dominant cost factor is labor. Placing a value on an employee’s time is more difficult than knowing the costs of components of a physical good.

SERVICE EQUALS PROFITS

Through the 1980s and early 1990s, many firms jumped on the service bandwagon, investing in service initiatives and promoting service quality as ways to differentiate them and create competitive advantage. Many of these investments were based on faith and intuition by managers who believed in serving customers well and who felt in their hearts that quality service made good business sense. Indeed, a dedication to quality service has been the foundation for success for many firms, across industries. Since the mid-1990s firms have demanded hard evidence of the bottom-line effectiveness of service strategies. Fortunately, researchers are building a convincing case that service strategies, implemented appropriately, can be very profitable. Work sponsored by the Marketing Science Institute suggests that corporate strategies focused on customer satisfaction, revenue generation, and service

quality may actually be more profitable than strategies focused on cost cutting or strategies that attempt to do both simultaneously (Rust, Moorman, and Dickson, 2002). Research from the Harvard Business School builds a case for the “service-profit chain,” linking internal service and employee satisfaction to customer value and ultimately to profits (Heskett *et al.*, 1994). Furthermore, considerable research has shown linkages between customer satisfaction (often driven by service outcomes) and profits (Anderson and Mittal, 2000). The University of Michigan American Customer Satisfaction Index (ACSI) provides data suggesting that customer satisfaction is directly linked to shareholder value. Firms in the top 50% of the ACSI rankings show significantly higher shareholder value than do firms in the bottom 50% (Fornell, 2004). An important key to these successes is that the right service strategies are chosen and that these strategies are implemented appropriately and well.

CONCLUSION

Services marketing strategy focuses on delivering processes, experiences, and intangibles to customers rather than physical goods and discrete transactions. Delivering experiences successfully and building customer relationships are complicated undertakings involving many different strategies and tactics. Although companies have often found it difficult to attack service problems in an organized manner, a well-established model called the gaps model focuses on the customer and describes the approaches necessary to close the gap between customer expectations and perceptions. Figure 1, the full gaps model, shows that closing the all-important customer gap is a function of closing four gaps on the service provider side: the listening gap, the service design and standards gap, the performance gap, and the communication gap. Each of these gaps involves concepts and tools designed to minimize the gaps, and these were discussed in this article.

supply chain management strategy

John T. Mentzer and Terry L. Esper

INTRODUCTION

No firm is self-sufficient, as organizations have always relied on external trade partners for access to necessary resources. The contemporary realities of increasing competitive pressures, environmental uncertainties, and customer demands have heightened the strategic imperative for integration across functions and organizations in order to stabilize this resource access and exchange. As a result, many firms have begun to focus attention on supply chain management (SCM). *Supply chain management* is defined as “the systemic, strategic coordination of traditional business functions and the tactics across these business functions within a particular company and across businesses within the supply chain, for the purposes of improving the long-term performance of the individual companies and the supply chain as a whole” (Mentzer *et al.*, 2001, p. 18).

While the emerging definitions rightly consider SCM to be a cross-disciplinary concept, the fact remains that most academic research on SCM has focused on developing conceptual and theoretical frameworks that define what supply chains are, and exploring the processes associated with managing them. Noticeably lacking is extensive dialogue on the elements of SCM strategy. Academics and practitioners have primarily emphasized the execution of SCM processes, many times without appropriate strategic direction and alignment.

Generally speaking, the manifestation of a lack of strategic emphasis in SCM is cost inefficiency and/or customer service ineffectiveness. While the overarching paradigm in SCM has been to focus on efficiency and process optimization, this has often overshadowed the importance of managing supply chains effectively. In other words, the operations cost imperative has often taken precedence over the marketing customer service imperative. However, it is important to match supply chains with specific product characteristics and market conditions (i.e., Fisher, 1997; Lee, 2002). In essence, the underlying issue is ensuring that a firm's supply chain is

constructed and managed in a way that effectively aligns with the needs and issues associated with customer demand and other environmental market forces, or, stated another way, ensuring that the supply chain is positioned for customer service effectiveness. This inherently involves purposively selecting and aligning supply chain exchange partners that are capable of supporting the strategic emphasis of the supply chain necessitated by product and market characteristics. As such, SCM strategy consists of aligning all companies involved in a supply chain with respect to product, market, and supply characteristics.

The key aspects of SCM strategy and some of the key facilitators of effective SCM strategy recognition and implementation are highlighted here. Toward that end, an overview of effectively defining the supply chain strategic emphasis is first discussed, followed by a discussion of supply chain design. The two fundamental facilitators of SCM strategy – demand and supply integration and supply chain orientation – are then described. Finally, concluding thoughts are offered, particularly emphasizing the marketing implications of SCM strategy.

SCM STRATEGY

SCM strategy involves two interrelated activities. To maintain acceptable levels of cost efficiencies and customer service effectiveness, firms must define the appropriate “goal” or strategic emphases of their supply chains. Although this is an important foundational principle of SCM strategy, it is not sufficient to arrive at a strategically relevant supply chain emphasis without the supply chain structure that supports the goal. Thus, in addition to strategic emphasis definition, SCM strategy involves effective supply chain design, whereby the structure of the supply chain is strategically architected.

The essence of SCM strategy lies in the fit between a firm's supply chain strategic focus and its structural support for effective SCM. The successful creation of a SCM strategy requires a high degree of *fit* between the identified emphasis and the supply chain structure. Fit is central to organizational success, and the best performing organizations establish strategies that closely fit the requirements of their environment

2 supply chain management strategy

(Chandler, 1962). Further, the concept of fit has been extended to the supply chain environment, with a high degree of fit seen when member organizations align strategies in pursuit of common supply chain goals (Defee and Stank, 2005).

Defining the supply chain. Perhaps one of the most breakthrough ideas in evolving thought concerning supply chains is that they are not, and should not be, managed all the same. Given that products vary in demand patterns, and markets and competition vary in levels of stability, supply chains must be managed with a particular strategic emphasis. While all supply chains are, conceivably, different, there are different generic “types” of supply chains that suggest different strategic emphases.

Fisher (1997) distinguished between supply chains that should emphasize efficiency and those that should focus on responsiveness. According to Fisher, an efficiency-focused supply chain is one that places significant emphasis on cost reduction and inventory minimization. Responsive supply chains emphasize flexibility and responsiveness, often manifested through higher inventory safety stock levels and product customization. The criterion for defining the strategically appropriate emphasis is the nature of end products within the supply chain. Fisher contended that products can be generally characterized as either functional or innovative, where functional products are relatively low profit-margin products whose demand can be forecasted and variability predicted. Innovative products are characterized as having low demand predictability and often having higher profit margins, as they are typically new products or new variations of functional products. As such, Fisher suggested that the key to effective SCM is ensuring that efficiency-focused supply chains are aligned with functional products and responsive supply chains support innovative products. Hence, SCM effectiveness is based on the proper alignment of product characteristics and supply chain strategic emphases.

Lee (2002) provided a framework that essentially builds on the work of Fisher by adding the dimension of supply source stability. The Lee framework suggests four strategic emphases,

two that are similar to the Fisher strategies, and two that deal specifically with supply environments that are relatively unstable. In particular, Lee suggests risk-hedging and agility as two strategic foci that emerge when the assumption of supply-side stability is relaxed, and relatively unstable supply markets are an issue. Again, the key idea is to define appropriate supply chain strategic perspectives depending on the nature of the external environment.

Goldsby, Griffis and Roath (2006) elaborated on this same concept in a manner quite similar to Fisher and Lee, although they referred to lean and agile supply chains. Furthermore, they discussed a postponement model as being “leagile,” whereby the strategic emphasis is to leverage a hybrid approach, thus realizing benefits associated with both strategic emphases. This essentially entails operating with a lean emphasis until a certain point in the supply chain where operations become more agility focused. The key to “leagile” strategic operations is understanding when to most effectively convert from a lean focus to an agile focus. Again, this key juncture is often dictated by environmental characteristics, further supporting the notion of fit.

These strategic emphasis frameworks support the idea that supply chain strategy involves defining the appropriate strategic focus that should underscore SCM processes. Hence, supply chains emphasizing efficiency or “leanness” will have a certain manner in which inventory exchange and other supply chain exchange processes are managed and optimized, whereas supply chains more aligned with responsiveness should manage inventory investment, resource allocation, and exchange using different approaches. The ultimate goal is cost efficiency and customer service effectiveness; however, the strategically managed supply chain is one that emphasizes the appropriately defined means to that end.

Designing the supply chain. In addition to defining the strategic emphasis of a supply chain, it is important to design a supply chain that can effectively implement the defined strategic focus. While the full extent of the supply chain design concept is beyond the scope of the present discussion, the essence of supply

chain design can be captured by highlighting its core element – supply chain partner selection.

As previously mentioned, the supply chain concept has grown in popularity and ubiquity primarily because of the need for firms to maintain and manage access to necessary resources. As such, it is inevitable that firms will have to find resource exchange partners with which to engage. The key is to ensure that supply chain partners are capable of supporting and executing the defined strategic emphasis that environmental conditions necessitate. Two of the most important partner selection criteria are organizational compatibility and network structure, as they are conceptually broad enough to capture many of the issues that are associated with effective supply chain partner selection, and, ultimately, supply chain design.

Organizational compatibility. Organizational compatibility refers to the extent to which supply chain partners possess cultures, business objectives, managerial philosophies, and decision styles that are similar to, or complement, each other. The more similar or complementary these areas of the firms, the more likely a level of strategic agreement will exist that can support the necessary coordination of flows. This element is particularly important when firms are attempting to support the execution of a particular strategic emphasis across the supply chain. For example, when it is necessary to focus on responsiveness and agility, it will be difficult to appropriately exchange with a supply chain partner that has a very lean and efficiency-oriented culture and managerial philosophy.

Issues such as employee empowerment and organizational structure may also impede some of the strategic exchange efforts if the organizational representatives are not equally empowered or authorized to make strategic decisions related to the management of coordinated flows. Again, using the agility strategic emphasis as an example, it will prove challenging to execute such a strategy with supply chain partners that do not empower SCM personnel to make decisions in a timely manner. Agility requires a significant amount of change management and dynamism. As such, supply chain managers engaging in more agile or responsive exchange

must be capable of making strategic-level decisions, often in the face of significant time pressure. Partner selection to support an agile strategic focus should, therefore, emphasize the degree to which representatives of potential partners are capable of engaging in agile and responsive decision-making.

Coordination of supply chain flows is not an easy task. The integration and synchronization of processes takes much time, effort, and investment. Furthermore, information sharing, which is such a fundamental feature of SCM, often requires a willingness to share sensitive information with supply chain partners. It is, therefore, important that there is sufficient managerial support within each partner firm to effectively invest the resources necessary to make coordinated flows a reality. This requires top managers to serve as champions of the coordination effort and provide organizational representatives with the level of empowerment, flexibility, span of control, and resource allocation necessary to support the intricacies of coordination in the supply chain.

In brief, organizational compatibility is about strategic alignment. In order for a defined supply chain strategic focus to be effectively implemented and executed, all supply chain partners must be strategically compatible. This essentially involves designing a supply chain that emphasizes alignment; ensuring that each partner has an internal infrastructure (i.e., culture, objectives, and managerial philosophy) that can effectively support a desired strategic emphasis within the supply chain. Effective partner selection should, therefore, involve assessments of such organizational artifacts when supply chain partners are under consideration.

Network structure. At the heart of supply chain partner selection is the creation of a relational agreement that will support significant resource exchange. While engaging in partner selection, supply chain managers must also consider the network implications of these relational agreements. In particular, it is important to be mindful of how selecting certain supply chain partners will impact the complexity and risk structure of the overall supply chain network. This is of particular concern in

4 supply chain management strategy

contemporary supply chain structures, as global supply chains have become much more popular.

Geographic proximity, for example, is often an environmental element that can enhance integrated relationships. This issue is of significant importance when considering coordination in a global supply chain context. The ability to be located near each other is quite difficult when exchange partners are global. Technological innovations such as teleconferencing and simple e-mail communication have significantly reduced this barrier. However, close geographic proximity is still an important issue in coordinating flows with supply chain exchange partners. Many large organizations often require key customers and suppliers, with whom coordination is extremely necessary, to develop satellite locations in close proximity to their facilities. This allows for more seamless coordination and exchange flows, as well as easy access to customer/supplier support personnel.

Overall, the issue is managing complexities and risk in the supply chain network structure. This is of particular importance when one considers the different strategic emphases that govern supply chains. For example, a prevalent difficulty is managing lean processes in global supply chains. The reduction in geographic proximity associated with managing global supply chain exchange has often increased lead times, managerial complexities, and operational risks. Such complexities and risks are very difficult to justify when attempting to focus on lean and efficient operations. Hence, many supply chain managers have opted to reduce global partner selection efforts to effectively support the lean strategic supply chain emphasis. The key is selecting partners that allow for a supply chain network that effectively supports the appropriate strategic emphasis.

When considered in concert, SCM strategy involves assessing the characteristics of the supply and demand environments to define a strategic emphasis that allows for optimal customer service effectiveness, and design a supply chain structure that can appropriately execute. This involves the notion of “fit” aligning environmental forces with the focus and network of exchange management along the supply chain. Hence, supply chain managers should determine if the supply chain

should emphasize efficiency, responsiveness, risk-hedging, or a hybrid approach such as a “leagile” focus, then design the appropriate supply chain by effective and aligned partner selection and network structuring.

FACILITATORS OF SCM STRATEGY

In order to successfully engage in SCM strategy, there are certain necessary facilitators. A significant impediment to thinking about the supply chain strategically is a lack of emphasis on SCM within firms, and a lack of effective communication across the organization. Firms that are more often “best in class” in managing supply chain processes have an internal infrastructure that supports strategic SCM thinking and execution. This essentially involves open lines of communication and exchange between the demand and supply sides of the firm, and an overall internal orientation that places strategic value on the role of SCM in supporting the firm’s competitive positioning in the marketplace.

Demand and supply integration. As depicted in Porter’s (1985) value chain framework, there are two primary sets of processes through which a firm creates value for its customers by moving resources and information along the supply chain: demand-focused processes consisting of marketing, sales, and customer relationship management activities; and supply-focused processes consisting of inbound logistics, operations, and outbound logistics. Historically, firms have invested resources to develop a core differential advantage in one of these areas – but rarely in both – often elevating the importance of one area at the expense of the other. The manifestation of such an approach is what Drucker (1973) has referred to as “The Great Divide” – separating the processes used to plan for and manage customer demand from those required for supplying the resources and operational dexterity to meet that demand.

Demand-focused firms tend to create value through an emphasis on effectiveness in serving customer needs at the expense of efficiency, whereas supply-focused firms tend to create value through an emphasis on efficiency at the expense of effectiveness. Too often, however, the traditional isolation of demand

and supply processes results in customer service ineffectiveness, manifested through mismatches between demand (i.e., shortages of products that customers want and/or surpluses of products that are not wanted), and supply (i.e., what is actually available in the marketplace).

Recently the concept of “demand and supply integration” (DSI), the balancing of demand and supply market information and business intelligence through integrated knowledge management processes to strategically manage demand and supply activities for the creation of superior customer value (Esper *et al.*, 2010), has received attention. This essentially entails a joint consideration of demand and supply-side information and processes to make more informed supply chain decisions throughout the firm. By simultaneously considering applicable market developments from both upstream and downstream forces, organizations are poised to exploit and leverage efficiency-focused operations while maintaining relevant levels of effectiveness.

An application of the DSI concept is sales and operations planning (S&OP), a tactical-level process for balancing and matching supply and demand plans. The S&OP process often focuses on making decisions about how to enhance demand when supply exceeds demand (e.g., increased advertising expenditures, pricing adjustments, new promotional activity), or how to dampen demand when demand exceeds supply capacity (e.g., reducing advertising, raising prices, discontinuing promotional activity, and incentivising customers to switch to other products and services). Again, the focus is on taking a balanced and comprehensive approach to managing supply and demand forces and processes.

DSI is, therefore, an important facilitator of SCM strategy because it supports the type of communication and strategic consideration that is necessary to make informed strategic SCM decisions. To reiterate, the core of SCM strategy is designing and managing operations within the supply chain that fit both demand and supply-side market characteristics. Firms that suffer from lack of integration run the risk of designing and managing their supply chain in a way that does not fit their environmental structure. For example, very supply-focused firms often emphasize “leanness” and efficiency

in managing their supply chain. Yet, without involvement from the demand side of the firm, it is possible that a more responsive supply chain is required based on market demand unpredictability. Likewise, demand-side orientation may result in an emphasis on responsiveness and agility, where in actuality the level of supply-side stability dictates more of an emphasis on lean operations. Thus, it is difficult to ensure an aligned strategic supply chain definition and design if there is not a level of integration to support the knowledge of what type of supply chain both the supply and demand environments necessitate.

In addition to DSI, the firm must embrace the SCM concept. Even if a firm effectively engages in DSI, and allows for the joint consideration of demand and supply market information to make decisions, it does not automatically mean that the firm will leverage this information for SCM. An additional facilitator of SCM strategy is an organizational infrastructure and philosophy that supports SCM.

Supply chain orientation. Supply chain orientation (SCO) is defined as “the recognition by a company of the systemic, strategic implications of the activities and processes involved in managing the various flows in a supply chain” (Mentzer *et al.*, 2001, p. 14). Hence, while SCM focuses on the management of exchange flows within and across the members of the supply chain, SCO emphasizes the strategic awareness and embracing of SCM within an individual supply chain firm. SCO is a necessary antecedent to effective SCM, which suggests that an organization must first look inward before it can effectively engage in strategic management of supply chain processes (Min and Mentzer, 2004).

The underlying premise of the SCO concept is the notion that effective implementation of SCM requires the firm to place strategic emphasis on the internal infrastructure, or culture, necessary to facilitate SCM exchange. In essence, SCO represents a shared value and belief system that aids in understanding how the organization should strategically manage its supply chain, and the behavioral norms needed inside the organization (Deshpande and Webster, 1989). This suggests that organizations possessing an SCO

6 supply chain management strategy

approach SCM differently from firms that are less inclined to view SCM strategically.

SCO has been viewed from both strategic and structural perspectives. The strategic SCO paradigm builds on the original conceptualization of the construct, where SCO was conceived as a philosophy focused on the implications of managing supply chain flows (Mentzer *et al.*, 2001). It conceptualizes SCO through an emphasis on the importance of strategic direction in managing supply chains. As such, the nature of this perspective involves making a strategic choice to compete on the basis of supply chain capabilities (Defee and Stank, 2005) and utilizing this strategic emphasis to drive the performance of strategic business units within the firm (Stank *et al.*, 2005). The strategic SCO perspective encourages firm personnel to act in a manner that manages flows from supplier to customer, taking a systems approach to viewing the supply chain holistically rather than as constituent parts, and seeking integration, synchronization, and convergence of intrafirm and interfirm operational and strategic capabilities (Min and Mentzer, 2004).

The structural SCO perspective, on the other hand, emphasizes organizational artifacts that facilitate SCM. For example, Min, Mentzer and Ladd (2007) suggested that SCO involves building and maintaining internal behavioral elements that facilitate relational exchange. Mello and Stank (2005) focused on defining SCO as cultural elements that support the organization's structure. They suggested that supply chain oriented organizations should behave in a way that facilitates trust, commitment, compatible supply chain partners to cooperate with, and top management endorsement. Though not referring to as SCO per se, Trent (2004) highlighted intrafirm structural elements necessary for effective SCM. This perspective focuses on an intrafirm structural management approach that facilitates effective SCM through emphasis on the behaviors, systems, and cultures necessary for integrated supply chain exchange.

Considering both perspectives leads to the conceptualization that a supply chain-oriented firm not only places strategic emphasis on systemic, integrated SCM, but also aligns this strategic thrust with an intraorganizational structure that capitalizes on this strategy.

The strategic perspective alone is not enough, because it requires structural support for effective implementation. Furthermore, the structural perspective does not, in and of itself, provide the necessary strategic direction to undergird the development and management of the structure. Hence, both perspectives seem to capture the true essence of the SCO concept.

CONCLUSION

The key elements of SCM strategy are to define a strategic emphasis for the supply chain, and to design the appropriate upstream and downstream supply chain to support this emphasis. This entails developing a vision of the supply chain to meet the market and supply characteristics faced, selecting appropriate supply chain partners, and building an efficient and effective network structure.

This is difficult to implement without the definitional and design influences of DSI and an SCO. DSI provides the orientation and processes to match market demand with supply chain capacities. SCO provides a cultural awareness that thinking about the supply chain strategically is of relevance and importance. One of the primary impediments to strategic SCM is that the firm does not value SCM, that is, its strategic role has not been defined. Hence, a key facilitator of SCM strategy is the development of an internal awareness and appreciation for SCM and how leveraging SCM processes for competitive positioning contributes to effective marketplace differentiation.

Many executives cannot cite a consistent, or even well-thought-out, definition of what SCM means in their company. It is perhaps axiomatic to say that design cannot be accomplished if what is being designed has not been first defined. Thus, companies trying to pursue a competitive advantage through SCM must first define their market and supply characteristics and related DSI implications, define what supply chain these characteristics necessitate, design the supply chain that will meet these definitions, and then select the supply chain partners to pursue this strategic vision.

Of course, the tactics of relational contracting, trust building, performance assessment, and reward sharing, and regular communication

between supply chain partners is critical, but these are more in the realm of the management of the supply chain, given an overarching SCM strategy. This, of course, leads to another vital managerial implication – companies successful at supply chain strategy and management must constantly reassess the factors mentioned in the previous paragraph and make certain they are still in concert with the managerial implementation of the latter factors.

The definitions open a fascinating vista of questions to be investigated concerning the definition, design, and management of supply chains. However, more work is needed to define the domains and dimensions of each of the theoretical constructs that precipitate from the discussion above. What broader, extant theories can be brought to bear on this definitional effort? This also leads to work on developing measures of each perspective. Subsequently, a myriad of questions present themselves. Does this process of definition, design, and implementation affect supply chain performance overall, and the performance of the specific firm with the SCM strategy and its partners? Are there significant differences in the distribution of rewards between these two groups, and are these differences seen as “unfair” by supply chain partners? Does the nature of the definition, design, and implementation activities vary across global cultures, and if so, does it affect supply chain strategy and management? Answers to these questions, and many other questions that will result from future thinking, should provide a rich body of knowledge for both studying SCM and using SCM for competitive advantage.

SWOT analysis

Srini Srinivasan

Business scholars and managers have long been interested in understanding the sources of competitive advantages of firms (Barney, 1995). Researchers at Harvard Business School, investigating the drivers of organizational performance, formalized SWOT (strengths, weaknesses, opportunities, and threats) analysis as a strategic tool in managing organizations for better performance (Learned *et al.*, 1965). SWOT analysis posits that to compete successfully in the market place, organizations need to consider concurrently both internal and external factors – some of which may be favorable to the organization while others may not (Valentin, 2001). In the SWOT analysis, internal factors that drive firm performance are broadly classified into strengths and weaknesses. Businesses derive their strengths from superior skills and tangible and intangible resources that help them to perform better in the market place and thwart competition. Weaknesses are deficiencies and constraints that prevent a firm from performing optimally or succeeding in the market place (Day, 1990). SWOT analysis also places emphasis on identifying relevant external factors that impact firm performance, and it broadly classifies them into opportunities and threats. Opportunities are trends and events outside the business that can significantly improve firm performance if appropriate actions are taken by the organization. Threats are environmental factors, which, in the absence of proper strategic response, are likely to result in significant decrease in firm performance and erode its competitive advantage (Aaker, 2005). A thorough SWOT analysis helps firms to build strategies that utilize their strengths and neutralize their weaknesses.

Though SWOT analysis was conceptualized more than four decades ago, it is still popular among executives owing to its simplicity and ease of use (Piercy and Giles, 1989). It is considered useful as it provides a simple framework for managers to brainstorm and map how they perceive their organization and their business environment. However, some researchers feel that the open nature and unstructured method

of SWOT analysis offer little guidance to users on where to search for the variables or what to do after identifying them (Panagiotou, 2003) and it is likely to identify too many factors, which have only minimal impact on firm performance. SWOT analysis is criticized for its static and descriptive nature and its inability to provide any analysis of the impact of these factors on firm performance. Weaknesses identified in the SWOT analysis can be overcome with additional resources, if suitable opportunities, which make the investment worth it, are present in the environment. The opportunities and threats identified are not static and sometimes threats appear in the guise of opportunities or vice versa. To improve the usefulness of SWOT analysis, Hill and Westbrook (1997) suggest that researchers provide more guidance on selecting the factors, and prioritizing them. Since the 1960s, when SWOT analysis was originally proposed, business disciplines have made strides in understanding firm performance and the factors that drive success (Day, 1990). SWOT analysis is likely to continue to be valuable in future, and business executives are likely to use it in conjunction with other strategic tools to create and extract value in the market place.

trademarks, proprietary marks, and brands

Philip C. Zerrillo

A *trademark* includes any word, name, symbol, device, or any combination, used, or intended to be used, in commerce to identify and distinguish the goods of one manufacturer or seller from goods manufactured or sold by others, and to indicate the source of the goods. In short, a trademark is a brand name.

The trademark is often equated with its historical precursor, the regulatory production mark. The regulatory production mark has its origins in the crafts guilds of Europe, most commonly believed to have started with the cooper's guild. Craftsmen would affix their mark to the inside of the trunks they produced as a means of identifying the work of their craftsman or guild.

A trademark can be registered, and become a "registered trademark" when it is filed with a government licensing office. (i.e., in the United States it is the US Patent Office) and granted registered status. These registered marks will then carry a ® to denote their legally registered status.

The *proprietary marks*, unlike the regulatory production mark, do not designate who the makers of the product are but rather who the owners of the goods are. In cases of shipwreck or piracy, the proprietary mark served as a useful means for sorting and recovering the dislocated goods. In the southwestern United States the cattle industry has a long and storied history with proprietary marks as the cattle were "branded" by burning the hide with a proprietary mark. This mark did not signify the maker or even the animal's breeder, but rather the owner. These marks did allow for the cattle to be sorted and recovered when pasture fences were broken and the herds were mixed, or when a rustler stole the herd.

A *brand*, as defined by the American Marketing Association (AMA), is a distinguishing name and/or symbol (such as a logo, trademark, or package design) intended to identify the goods or services of either one seller or a group of sellers, and differentiate those goods or services from those of competitors.

From a legal standpoint, a brand thus signals to the customer the source of the product and

protects both the customer and the producer from competitors who would attempt to provide products that appear to be identical. The European and North American courts initially developed laws to protect the brand names and marks from would-be infringers as a means to protect consumers from the tort of fraud. In other words, the primary concern was to keep the consumer from being taken advantage of by producers that would tread on the good name of well-known manufacturers to pass off inferior goods. Over the past 70 to 90 years the emphasis of the law has swung toward not just protecting the consumer from fraud, but the protection of the business assets that brands represent (Peterson, Smith, and Zerrillo, 1999). In practice, from a legal standpoint, the emphasis of brand protection has begun to model property law.

The managerial emphasis of branding has been to move beyond commodities to branded products in order to reduce the importance of price in the purchase decision by accentuating the basis of differentiation. In other words, a brand tells us whose product it is, and whose product it is not, so that we may differentiate the goods from those of other producers and provide a basis for loyalty. But at the end of the day, the goal is to get away from price as the reason to buy a good or service. For instance, in the absence of any other information about two bags of cement, say cement A and cement B, the purchaser will normally buy the cement that costs less, as it is a way of reducing their risk. But, when you put cement A in a shiny bag, and inform would be buyers that it is fast drying, has a 30-year life expectancy, and can be submerged in 200 meters of water, the consumer may be willing to pay more for A than B. Thus, the ability to differentiate the offering and promote features and performance rather than price is a means of moving beyond commodities.

The value of brands are widely studied and discussed. They often dwarf the value of plant and equipment when firms and their brands are purchased. (see PERCEPTION OF BRAND EQUITY). Investment in brand-building activities is often a struggle within the modern organization. On the one hand, the brand is a long-term asset and it is easy to temporarily cut expenditures on brand building activities such as sales, advertising, and trade promotion voluntarily as a

2 trademarks, proprietary marks, and brands

means to increase contribution margins. Moreover, the struggle within firms often centers around the realization that while brands have great value (*see* BRAND VALUE), the activities that build them (advertising, sales-force promotion, channel management) are treated as operating expenses rather than as investments by the finance department.

a framework for creating value propositions

James C. Anderson and Gregory S. Carpenter

DEFINITION

What is a customer value proposition, or simply, a value proposition? A *value proposition* is the statement of those few points of difference that create a compelling reason for a customer to select one market offering relative to competing alternatives.

FRAMEWORK FOR CREATING VALUE PROPOSITIONS

The three primary factors in constructing value propositions that target customers find persuasive are frame of reference, points of parity, and points of difference. The *frame of reference* is the set of potential competing alternatives that a customer considers. *Points of parity* are the elements of the market offering on which the customer views the offerings as essentially the same. *Points of difference* are the elements of the offering on which the customer views one offering as noticeably superior.

Potential value propositions can be evaluated on three criteria: distinctiveness, measurability, and sustainability (Anderson, Kumar, and Narus, 2007). *Distinctiveness* captures the extent to which the value proposition is uniquely able to deliver on a claim relative to alternative offerings. *Measurability* is the extent to which the value proposition can be substantiated in tangible ways, such as in monetary terms. *Sustainability* captures how long the uniqueness the value proposition conveys is expected to last.

VALUE PROPOSITIONS FOR CONSUMER MARKETS

In consumer markets, one way to understand value is to consider that customers seek to achieve goals. Goals take two forms: positive outcomes we hope to achieve and negative outcomes we hope to avoid. Achieving their goals creates a problem for buyers to solve. Market offerings create value for buyers by proposing solutions to their problems. Royal Caribbean cruises offer one example.

To solve problems, buyers often consider a number of alternatives. On vacation, some might seek relaxation, others seek a cultural experience, and still others might seek to indulge a personal goal (learn Italian). Royal Caribbean identified a group of consumers who seek adventure on vacation. They call this group “explorers.” For explorers, vacation options include helicopter skiing, scuba diving, or bicycle touring.

Although, all these options share the element of adventure, each option offers a distinctly different experience. In comparison, a cruise is seen as sedate, unexciting, and for older people. A cruise, however, does have one significant point of difference with other vacations – it offers variety in terms of locales and activities.

To craft a value proposition, Royal Caribbean developed the idea that variety can be a dimension of adventure – a cruise offers *multiple* new experiences that are not possible with a single-adventure holiday. By offering multiple novel experiences, a Royal Caribbean cruise can offer a greater sense of adventure.

The value proposition they developed reflects this essential insight: Royal Caribbean is the vacation option that creates unexpected experiences that brings out the explorer in me.

As a result of this new value proposition, brand awareness and preference have increased among target buyers, the customer mix is increasingly younger than other cruise lines, and booking has been growing.

VALUE PROPOSITIONS FOR BUSINESS MARKETS

Management practice research (Anderson, Narus, and van Rossum, 2006) has recommended that suppliers in business markets construct *resonating focus* value propositions, which consist of “the one or two points of difference (and, perhaps, a point of parity) whose improvement will deliver the greatest value to the customer for the foreseeable future” (p. 93). The rationale for resonating focus value propositions is that in a business world where customer managers are taking on greater responsibility and are increasingly pressed for time, to be successful, suppliers must deliver customer value propositions that are simple, yet powerfully captivating. They do this by making their

2 a framework for creating value propositions

offerings superior on the few elements whose functionality or performance matter most to target customers, demonstrate and document the value of this superior performance, and communicate it to target customer managers in a way that conveys to them that the supplier understands their business concerns and priorities.

A resonating focus value proposition is preferable to more commonly used value propositions, which consist of either all benefits that the customer receives from a market offering or all favorable points of difference that an offering has relative to the next best alternative.

marketing warfare strategies

Daniel Laufer

Marketing warfare strategies are competitor-centered strategies borrowed from the field of military science and applied in a marketing context. According to Rindfleisch (1996), advocates of this approach suggest that both marketing and the military are very similar, and both fields share “(i) two or more opposing forces; (ii) competition for a limited and valuable resource; (iii) a zero-sum orientation in which gains come at the expense of competitor losses; and (iv) defined rules of engagement in which one competitor attacks while the opposing defends.” This approach was popular in the 1980s, whereas in the current era of relationship marketing this approach has become less relevant. Also, an increased awareness of differences between business and military organizational cultures raises questions of the applicability of military strategies in a business context.

In 1981, Kotler and Singh (1981) wrote a highly influential article about how warfare strategies can be applied in the field of marketing. This competitor-centered approach suggested that principles from military strategy can be applied to develop (i) business objectives; (ii) attack strategies; and (iii) defense strategies.

Kotler and Singh (1981) claimed that the concept of “principle of objective” derived from military science can also be applied to business objectives. The principle of the objective stated that “every military operation must be directed toward a clearly defined, decisive, and attainable objective” (Kotler and Singh, 1981 p. 33). According to Kotler and Singh (1981), in a marketing context the objective is usually described in terms of “crushing the competitor, reducing its share, or freezing its share” (Kotler and Singh, 1981 p. 33), and is contingent on the type of competitor the company is facing (market leader, similar-sized firm, or smaller firm).

After determining the objective, a company assesses how to wage war. Kotler and Singh (1981) introduced two types of strategies: attack

strategies and defense strategies. Attack strategies involve taking the offensive and seizing market share from competitors. These strategies include frontal attacks, flanking attacks, encirclement attacks, bypass attacks, and guerrilla attacks (Kotler and Singh, 1981). Defense strategies, on the other hand, involve fortifying one's position, or defending market share from competitors. These strategies include position defense, mobile defense, preemptive defense, flank-positioning defense, counteroffensive defense, and strategic withdrawal (Kotler and Singh, 1981).

Interest in marketing warfare strategies peaked in the 1980s during an era of slow economic growth. The economic downturn caused companies to seek growth opportunities primarily from gains in market share as opposed to increases in overall market demand. This encouraged companies to turn to competitor-centered strategies such as marketing warfare strategies. In addition, prominent military officers moved into key leadership positions during this time at business-related organizations which influenced the choice of corporate strategy due to the military experience of the new executives (Rindfleisch, 1996). Finally, large corporations turned to the military for guidance in creating an effective bureaucracy to run their organizations. This created similar organizational structures and policies and procedures, such as chains of command and standard operating procedures (Rindfleisch, 1996). Similarities between the bureaucracies encouraged a military mindset among business organizations which generated increased interest in marketing warfare strategies.

During the 1990s and 2000s, marketing warfare strategies became less relevant during an era of relationship marketing. A number of researchers questioned whether the business context is equivalent to a war despite the similarities on a number of dimensions (Rindfleisch, 1996). In particular, a zero-sum game mentality regarding winners and losers became less prevalent, and cooperation and coexistence among competitors became more the norm in many industries. In addition, there was an increased awareness during this time period of differences between the organizational cultures of businesses and the military. As Rindfleisch

2 marketing warfare strategies

(1996) points out, not all businesses are highly structured and “the type of highly structured and calculating strategic planning implied by marketing-as-warfare may be more fitting for companies with bureaucratic cultures and less appropriate for firms with more clan-like cultures” (Rindfleisch, 1996 p. 7).

causal research

Harmen Oppewal

Causality concerns cause-and-effect relationships between variables (*see* CONCEPT OF CAUSALITY AND CONDITIONS FOR CAUSALITY). Humans have a natural tendency to think in terms of cause-and-effect relationships and we use such relationships to “explain” the world we live in. As individuals, we continuously observe and monitor changes in our environment and infer from these changes what the likely cause is for some outcome. Knowing about causes is crucial for taking decisions about what actions to take, from small day-to-day decisions (“why am I feeling cold? – is the heating system on?”) to the most important issues in society (“is there global warming and what are its causes; will reduction of carbon dioxide emissions help reduce global warming?”). Whereas philosophers have debated for centuries whether causality exists, people use it, and rely on it.

The scientific process of generating, testing and revising ideas can be seen as an extension and refinement of the basic human processes of knowledge generation. In this, testing which relationships are causal and which are “spurious” is seen as one of the main aims of scientific research, both by scholars who aim to find the “truth” about what influences and determines observed phenomena, and by scholars and practitioners who are keen to just know “what works” (Dunbar, 1995). As an example in marketing, consider the role of satisfaction (*see* CUSTOMER-SATISFACTION RESEARCH). It is intellectually gratifying to know what determines satisfaction, but it is also very relevant practically for marketers to know what actions can be taken to increase satisfaction. Should a company invest in a loyalty card scheme in order to increase customer satisfaction and retention? Such investments will only be worthwhile if the scheme can be expected to indeed positively affect satisfaction and retention rates. Causal research is relevant even if it would lead to the conclusion that such schemes are *not* contributing, as in that case the company can better use its resources for other purposes. Identifying the cause of some

outcome can be as important as identifying if some factor is not a cause.

Causal research is research that aims to investigate causal relationships. Causal research therefore always involves one or more independent variables (or hypothesized causes) and their relationships with one or multiple dependent (or outcome) variables. In addition there may be “mediating” variables sitting between the independent and dependent variables, reflecting the causal process or mechanism. Causal *descriptive* research aims to establish the *effect* of the independent variable(s) on the dependent variable. Experiments are widely accepted as the best method for testing such effects, and the remainder of this article will focus largely on experiments. However, knowing an effect exists and its size is not equal to having insight as to why the effect exists. Causal *explanatory* research aims to describe the process of how an independent variable influences an outcome variable (Shadish, Cook, and Campbell, 2002). Explanatory research requires theorizing and the use of abstractions, or constructs, to identify why outcomes occur the way they do. Causal explanatory research can include the generation of new ideas and insights on the basis of literature research, participatory observation (*see* ETHNOGRAPHIC RESEARCH), focus groups (*see* FOCUS GROUPS AND DEPTH INTERVIEWS), and any other type of data collection, and can also use analogies or models from other domains. In science, there is no limit and restriction to idea generation, but to become an accepted theory the ideas have to fulfill basic requirements such as coherence and consistency, and the ability to explain phenomena that we have accepted (and that we are willing to continue to accept) as “facts” (Dunbar, 1995; Latour, 1987). This wider area of theory building and model specification will not be further discussed in this article but note the issue of *validity*, especially construct validity (*see* RESEARCH RELIABILITY AND VALIDITY; CONCEPT OF CAUSALITY AND CONDITIONS FOR CAUSALITY).

A particular and more formalized type of causal explanatory research concerns “causal modeling.” Causal modeling tends to be associated with *structural equation modeling* (SEM), which extends regression and factor analysis to

2 causal research

allow the measurement of “latent” constructs and their causal relationships within one statistical framework (see STRUCTURAL EQUATION MODELING). In SEM the assumed causal relationships between constructs are displayed in a “path diagram,” which is a set of boxes and arrows showing how the constructs influence each other. Causal modeling can also be considered more widely as to include the various regression-based models used in econometrics that capture the relationships between independent and dependent variables in various types of statistical formulations (see MULTIPLE REGRESSION). The key feature of all these methods, whether SEM or econometric models, is that they are typically applied to data that are either cross-sectional or, if time series are used, lack a proper control condition. They capitalize on the use of statistical theory and mathematical functions to determine and disentangle the effects of independent variables, and the theoretical constructs they represent, on dependent variables (or constructs). Whereas they are very sophisticated and potentially very useful for assessing such relationships, their application to cross-sectional, uncontrolled data shows that they cannot fully establish or test the causal nature of relationships in the data. They can only attempt to *statistically* separate possible causes from noncauses. In contrast, experiments aim to separate and control various causes *by design*. This is why conclusions from experiments typically have greater *internal validity*; they are a better basis for establishing whether the independent variable was the true cause of the effect observed for the dependent variable. Experimental control, however, cannot always be achieved and further, has often the disadvantage of limited external validity. In this respect, the design and statistical approaches complement each other and in practice are often used together to maximize the validity of the knowledge gained from a research project (see VALIDITY IN EXPERIMENTATION).

PRINCIPLES OF EXPERIMENTAL DESIGN

Basic terminology. Although, many people associate scientific experiments with laboratories, white coats, and guinea pigs, experiments have a much wider use. Experiments are

sophisticated versions of trial and error, or plan-act-evaluate cycles of behavior: we try something, observe the outcome, and draw conclusions regarding the effects of our actions.

We now turn to discussing the key concepts and rationale of experimentation and experimental design. Before discussing various types of design it is useful to introduce the notation system to graphically display the characteristics of the various designs and discuss the principles of design and analysis (Cook and Campbell, 1979).

Each test unit in the experiment undergoes a sequence of events consisting of *treatments* (X), representing variations of the independent variable, and produces *observations* (O), which are measurements of the dependent variable. Figure 1 displays three *preexperimental* designs. They each include a treatment group and one or more observations. Neither however has a comparison or control group to act as a benchmark for assessing the effects of the treatment. These designs therefore cannot automatically rule out the “third variable” alternative explanations that threaten the internal validity of conclusions drawn from these designs (see VALIDITY IN EXPERIMENTATION). Suppose we conduct a study on advertising effectiveness. X represents “being exposed to an advertisement” and O is a participant’s response to a brand perception question (Figure 1a). If O is positive, can we infer that the advertisement exposure caused the positive effect? Not so, as many other variables will (also) have influenced the participant’s response. We could include a pretest measure as in Figure 1b. This “one-group pretest–posttest design” would allow observing how the brand perceptions have changed since the advertisement was presented, for example, if $O1$ and $O2$

Figure 1 Preexperimental designs.

had been observed with one week interval. However, this would not separate the advertisement effect, if it existed, from the possible effects of other events occurring between $O1$ and $O2$. Even if a longer time series (Figure 1c) had been observed, although providing a stronger basis for inferring the effect of X on O , it would still not account for events co-occurring with X .

Experimental designs include at least two groups (conditions), one being the experimental group and the other the control group. The *control group* does not receive the experimental treatment. An example is shown in Figure 2. $G1$ could be a group seeing the advertisement and then being asked to rate our brand, while $G2$ could be a group that does not see the advertisement, but still rates the brand. Comparing $O1$ and $O2$ will give an indication of the effect of X . However, there may be preexisting differences between $G1$ and $G2$, and these may be the underlying causes of observing differences on the values of $O1$ and $O2$. To overcome this issue experimental designs rely on *randomization (R)*. Experiments that use existing groups without randomization are called *quasi-experiments*.

Figure 3 presents a two-group *posttest only* experimental design. It is a posttest only design because the measures are only taken after the treatment (seeing the advertisement) has been administered. Each unit (participant) is in only one condition, and it is therefore a *between-participants* design. It is a true experimental design because individual test units are randomly assigned to the conditions.

Statistical rationale. We now explain the benefits of randomization. Suppose in the previous example $G1$ and $G2$ each consisted of 30 participants where each participant rated

$G1 : X\ O1$
 $G2 : \quad O2$

Figure 2 Two-group quasi-experimental design.

$G1\ (R) : X\ O1$
 $G2\ (R) : \quad O2$

Figure 3 Two-group posttest only experimental design.

the brand on a five-point scale. We could then calculate the means for both groups and test if they are statistically different using a standard t-test or *analysis of variance (ANOVA)* (see ANALYSIS OF VARIANCE AND COVARIANCE) (assuming the observations have been measured at interval level) (see PRIMARY SCALES OF MEASUREMENT). If $O1$ has a statistically significant higher (or lower) mean than $O2$ this will be attributed to group 1 receiving treatment X . This is because all preexisting differences between individuals were controlled by randomly allocating them to groups 1 and 2. Adopting the conventional 5% level of significance means that chances of observing this difference based on mere chance (or actually, based on the combined effect of all unobserved “third variables”) are less than 5%. That is, there is only 5% probability of drawing the conclusion that there is a difference if in “reality” there is no effect (this is called the *Type I error*). This percentage is normally deemed too low to accept the interpretation that the effects are caused by mere chance. Instead, the only other possible interpretation is accepted, which is that X caused the difference between $O1$ and $O2$.

If no significant difference is observed between $O1$ and $O2$ this may be either because there is really no effect of X , or the effect may have existed, but could not be detected. The latter means the design lacks sufficient “*power*” and the researcher runs the risk of committing a “*Type II error*”: falsely concluding there is no effect. This can occur firstly when the sample sizes for the two groups are too small. Means observed for smaller samples display a larger variance and it is therefore more likely that differences of certain size occur even if there is no effect of X (see PROBABILITY SAMPLING). The researcher then cannot decide whether the observed difference is because of a real effect of X or because of a mere chance. A second possible reason for not detecting a true effect of X on O is the influence of other (unobserved) factors on the variation in units’ scores for $O1$ and $O2$ (independently from X). These factors increase the variance in sample means for $O1$ and $O2$, making it difficult to detect any effect because of X .

These two reasons for a lack of power each have their own remedy : (i) the sample size can be increased, or (ii) the variation in the measures of *O1* and *O2* can be reduced. The effects of increasing the sample size are the same as for any random sampling: any doubling of precision requires a quadrupling of the sample size (or stated differently: precision increases with the square root of the sample size) (see PROBABILITY SAMPLING and STATISTICAL APPROACHES TO DETERMINING SAMPLE SIZES). Increasing the sample size is an obvious candidate for improving a design, but can be costly in terms of money and time. And if the researcher realizes the limited power only after the data have been analyzed (and no effects were found) it may be difficult if not impossible to replicate the exact experimental conditions to allow the collection of extra responses, especially given the requirement of random assignment. Merely topping up the numbers for one group is not sufficient; extra respondents should be randomly assigned as in the original experiment or one will end up with a quasi-experimental design.

Reduction in variance, which is the second method for enhancing power, can firstly be achieved by design. *Standardization* of test circumstances will reduce the variance in the dependent variable. Variance will further reduce if a more homogenous sample of participants is used, which is one reason why many consumer experiments in marketing are conducted on student samples (in addition to ease of access to such respondents by academic researchers). Instead of limiting the sample to a narrowly defined group of participants, it is also possible to include variables in the design that ensure that the sample can be treated as a set of homogenous subgroups. This is achieved by using *blocking factors* (discussed further below).

After the data have been collected, the variance can possibly be further reduced by means of statistical control. By including additional variables in the analysis that “pick up” or “explain” some of the variance in *O* the remaining variance to be explained reduces, thereby increasing the chances of detecting an effect of *X*, if it exists. In terms of data analysis this means that extra independent variables are included in the analysis as covariates using analysis of covariance (*ANCOVA*) or

multiple regression methods. (see ANALYSIS OF VARIANCE AND COVARIANCE; MULTIPLE REGRESSION) Good covariates are variables that themselves are not affected by the treatment and that correlate substantially with the dependent variable (Tabachnick and Fidell, 2007). Typical candidate covariates are demographics such as age or gender, attitude measures — or prior observations on the dependent variable, which are called *pretest scores*. The next sections will discuss the use of pretest scores and the use of blocking factors.

Including pretest scores. *Pretests* are observations obtained for each test unit prior to receiving the treatment. By including such pretest scores in the analysis, the statistical power of the analysis can increase substantially and a same size difference between the posttest means can now become statistically significant. Such a design is called a “*pretest–posttest experimental design*.” The basic form of this design is shown in Figure 4, for a case with one experimental and one control group. Note that pretest measures *O1* and *O3* are not used to directly assess the effects of *X*; they only act as control variables in the analysis. The actual analysis of a pretest–posttest design often involves recoding the dependent variables into a new variable representing the difference for each unit between the posttest and pretest scores.

In our example, we would for each participant calculate the difference between the pretest and posttest scores and use this value as the new dependent variable. This new measure will have less variance than the original scores because differences between participants’ use of the measurement scale have cancelled out.

Although there are clear advantages to having a pretest measure, one should be careful that pretest scores are not used to create experimental groups as this may introduce a biasing regression to the mean effect (see VALIDITY IN EXPERIMENTATION). Another main concern is that exposure to the pretest measurement

Figure 4 Pretest–posttest experimental design.

may influence the participants such that the posttest scores no longer reflect the effect of X as intended but instead reflect the effect of “seeing the advertisement and having been asked to answer a pretest score.” Such exposure to a pretest is a potential threat to the study’s validity as it may sensitize respondents to the brand (see VALIDITY IN EXPERIMENTATION).

A design that allows detecting and separating these possible “carry-over” effects from the pure effects of X is the so-called *Solomon four-group design*, shown in Figure 5.

Comparison of the means of $O2$, $O4$, $O5$, and $O6$ will allow inferring the effect of X with and without prior exposure to the measurement instrument as follows:

- Effect of X without pretest exposure = $O5-O6$.
- Effect of X with pretest exposure = $O4-O2$.
- Effect of pretest only = $O4-O6$.
- Effect of X accounting for pretest scores = $(O2-O1)-(O4-O3)$.

It is sometimes possible to make more efficient use of available respondents and increase the sample sizes for different conditions by having respondents complete multiple conditions. If respondents are not completing one, but multiple treatment-measurement sequences, then more observations are obtained from the same respondent. However, this gain in efficiency comes with a cost, similar to introducing a pretest. The exposure to the first treatment may have carry-over effects and change the response generated by the second and following treatments. The use of such “within-participants designs” therefore, requires special precautions and they should be used only after consideration of these possible biasing effects, and how to account for them in the analysis. One compromise solution is to administer the second treatment and measurement, but include a sufficient number of respondents to allow conducting the main analysis on the

basis of only the observations for the first treatment. This is shown in Figure 6. The first part of the design, with measures $O1$, $O3$, and $O5$, consists of a separate between-participants three-group design, and the total design is a mix between- and within-participants design. Analysis of within-participants designs typically involves so-called *repeated measures analysis*, which is a special type of MANOVA (*multivariate analysis of variance*) (Tabachnick and Fidell, 2007) (see REPEATED MEASURES ANOVA).

Using blocking factors. The general discussion so far has assumed that we always aim to assign experimental units randomly to the various treatment conditions. There is however substantial efficiency to be gained from the incorporation of the so-called blocking factors. *Blocks* are existing groupings of units that are assumed to show systematic differences in their scores on the dependent variable. By completely or partly repeating the experimental treatments within each of the blocks, these differences can be taken into account in the analysis. This reduces the variance in the dependent variable, thereby providing more scope for the effect of the experimental treatment to be detected.

If we expect males and females to differ in how they perceive the brand which is the focus of our study, it would be wise to use this information when designing the study. To use gender as a blocking factor, we would set up the study such that an equal number of males and females are randomly assigned to the experimental and control conditions. This consists of a *randomized block design*: all experimental conditions (seeing the advertisement versus not seeing the advertisement) appear equally often within all blocks (genders).

However, it is not always feasible to administer all treatments in all blocks. Suppose for our study we intercept shoppers in a shopping center and wish to study multiple brands. Because the

questionnaire will become too long we decide to ask each respondent about only two brands controlling for order in which the brands are presented. In this case, an *incomplete block design* may be considered, which means that only a subset of all treatments (brands) is administered in each block (position in the questionnaire as first or second brand) while it is ensured that each of the treatments appears equally often with each other treatment. Incomplete blocks are only available for a specific number of treatments and blocks (Montgomery, 2004).

Yet another type of blocking design is the *Latin square design*. This design can be used if two variables are used as blocking factors. Each experimental condition is administered to only one combination of variables while ensuring that each combination of blocking variable and treatment occurs equally often. In our example, if we included three brands per questionnaire and were also concerned about sample differences based on day of the week (as different days attract different types of shoppers), this could involve that we vary the order of presentation of the brands and day of the week, handing out only one version on each day, as shown in Table 1. Such a design assumes that effects of day of the week and order of presentation are independent of each other. Like incomplete block designs, Latin squares exist for only particular combinations of factors (Montgomery, 2004).

Factorial designs. So far we have considered only two or three experimental groups, each receiving one or two different experimental treatments or comprising a separate control group. Each treatment however can be made up of a combination of factors. An *experimental factor* is an independent variable describing one facet of the experimental condition or stimulus. Factor *levels* are the discrete and fixed conditions for the factor to which units are randomly

assigned.

Factorial designs have two or more factors that are “crossed” to observe all possible combinations of factor levels. The simplest factorial design is a 2×2 (“two by two”) factorial design, comprising four experimental groups. Although statistically there is little difference between adding a blocking factor and adding another experimental factor, the important conceptual difference is that experimental units are randomly assigned to the conditions of the experimental factor while the conditions of the blocking factor comprise previously existing groups. With blocking, the researcher has no control over the allocation of units to blocking conditions and therefore, differences between block means are merely descriptive and cannot be used to infer causal effects of the block factors.

The main advantage of factorial designs is that they allow studying the effect of changes in two or more factors at the same time. They therefore allow for the exploration and testing of interaction effects. An *interaction effect* is any effect on the dependent variable that depends on a specific combination of values of independent variables. Interaction effects can be analyzed and statistically tested using ANOVA or multiple regression. To interpret an interaction effect it is usually advisable to plot the effects in a line graph (see ANALYSIS OF VARIANCE AND COVARIANCE).

Fractional factorial designs. Factorial designs are very useful and are the backbone of a lot of experimental research. They however have one main limitation: as the number of factors increases, the number of conditions to be observed increases dramatically. Each addition of one two-level factor results in a doubling of the number of conditions. This is easy to see: a 2×2 has 4 conditions, a $2 \times 2 \times 2$ has 8, and so on. A factorial design of 7 two-level factors comprises 2^7 or 128 different conditions, a full factorial of 15 two-level attributes consists of 2^{15} or 32 768 different treatment conditions. This number of conditions will often be too difficult or expensive to produce and/or to administer.

To overcome this limitation, fractions of factorial designs are often used. *Fractions* are balanced subsets from the full factorial design. They have the property that although not all

| 8 | -1 | -1 | -1 | 1 | 1 | 1 | -1 |

possible interactions can be tested, at least the “main effects” of all factors can be observed and tested independently of each other. The smallest fractional factorial design with seven two-level factors comprises only eight treatment combinations; a fractional design for a study with 15 factors can be as small as only 16 treatment combinations.

To demonstrate the features of fractional factorial designs we follow up on our previous example of testing various advertisement formats. Suppose we wish to test how evaluations of our advertisement are influenced by various promotional and layout features, including mentioning of a price discount (yes or no), mentioning of product quality award (yes or no), order details (limited or full details), theme color (red or blue), advertisement size (small or large advertisement), font type (small or large font), and position on magazine page (top or bottom of magazine page). These are seven factors to consider. Each has two levels so the total number of possible advertisement configurations to test is 2^7 , or 128 configurations. We can create a balanced subset of only eight configurations as follows.

We start with a three-factor full factorial design in eight treatment combinations (Table 2). Each factor is coded +1 and -1 to indicate the two possible levels. The first three columns dictate the level used in each treatment, the remaining columns are only used in the analysis to estimate all possible (two- and three-way) interaction effects. So, we have directions for creating the variations of discount, award, order details and will estimate

their “main effects” from columns A, B, and C and use the remaining columns to estimate three two-way (or “first order”) interactions ($A \times B$, $A \times C$, $B \times C$), and one three-way (or “second order”) interaction ($A \times B \times C$). The codes in these seven columns describe all possible differences between the eight conditions.

Fractional factorial designs utilize these interaction columns and “overlay,” or *confound* them with new factors, assuming that none of the original interactions exist. This is the crucial assumption underlying fractional factorial designs: by assuming interactions to be nonexistent (or zero), they free up columns in the design table to be used as “main effects” columns for extra factors D to G, which similarly are assumed to not interact with any of the other factors.

Table 2 shows the full factorial design with three factors in eight treatments and demonstrates how the same design table can be used to generate a fractional factorial design with seven two-level factors. Across the eight conditions each factor level occurs equally often with each of the other factor levels. For example, there are four levels “1” for A and within these there are two occurring with level “1” for B and two with level “-1” for B; similarly there are two occurring with level “1” for C and two with level “-1” for C. This property can be tested by calculating the correlations between the seven columns in the design. All correlations should be zero. Designs as in Table 2 are called “*independent main effects plans*” or “*orthogonal designs*.”

The principle can be extended to include more factors and to include factors with more

levels. For example, a main effects plan for 15 factors can be constructed that includes only 16 treatment combinations. A main effects plan of 12 three-level factors can be constructed that includes only 27 treatment combinations. More complex designs can be created in various ways, including designs for combinations of two and three or more levels per factor.

The above demonstrates the main principle behind the construction of a fractional factorial design. Not all fractional factorial designs assume all interactions to be zero and not all of them confound main effects with two-way interactions. So-called Resolution IV designs allow estimating main effects independently of such interactions, and other designs even allow estimating some interactions; however this comes always at the cost of requiring larger numbers of treatments (Montgomery, 2004; Hensher, Rose, and Greene, 2005).

The principle illustrated here also does not always result in the most efficient design. For a particular applied problem more optimal combinations may exist, depending on the number of factors and factor levels, the amount of prior information about variation in the dependent variable, the cost of creating different conditions, and the expected sizes of the effects. It is beyond the scope of this article to discuss these more technical issues except for noting that recently substantial progress has been made in developing efficient designs for studies with larger numbers of factors, especially in so-called choice experiments (Street, Burgess, and Louviere, 2005). Catalogs of design plans are readily available or design plans can be generated using software such as SAS. SPSS includes a routine for generating main effects designs.

Fractional factorial designs have been used, in particular, in two related methods for studying consumer preference and choice, called *conjoint analysis* and *choice experiments*. In *conjoint analysis*, respondents rate the attractiveness or purchase likelihood of hypothetical alternatives that are presented to them one by one (see CONJOINT ANALYSIS). Instead, in *choice experiments* respondents repeatedly make choices between different alternatives (Louviere, Hensher, and Swait, 2000; Hensher, Rose, and Greene, 2005). Alternatives can be products, destinations, travel options, sites, or

any other relevant choice option. Alternatives are described by their main features, called *attributes*. These can be any feature like in case of travel options, mode of transport, destination names or types, travel cost, local attractions, accommodation types, and so on. Different combinations of attributes result in different hypothetical options. From the observed ratings and choices the researcher infers the relative importance of each feature, typically using regression-based methods. The approach uses experimental design methods, especially fractional factorial designs to create the different option descriptions.

CONCLUSION

The aim of most experimental research is to test causal relationships. Causal relationships are giving decision makers control and are a basis for deciding what actions to take to obtain desired outcomes. Experiments are powerful but require careful preparation. Also they can accommodate only a limited number of variables at any time. Experiments are therefore often conducted as a sequence of different tests. They are also typically only conducted after extensive exploratory research through interviews, surveys, or observational methods. The research literature obviously is another important source of information to allow the development of ideas in sufficient detail to make experiments worthwhile.

Finding a good design depends on the particular setting, what variables need to be controlled for, the opportunities for applying randomization, and the trade-off between internal validity, which requires homogenous conditions, and external validity, or the extent to which the test situation is representative of the target application situation. In addition to internal validity, which is about assessing causality, another main issue is construct validity: a treatment may have had a reliable effect and all alternative explanations have been ruled out, but often the question remains as to what is the actual “active ingredient” of the treatment, and does this active ingredient correspond with the constructs in our theories?

To conclude, experiments are the best method for testing causal relationships but only a limited

number of relationships can be tested in any applied setting. Understanding basic principles of experimental design is important even if one has no intention of conducting experiments as it will allow to better understand the limitations of other research approaches. Experimentation is not just a research approach; it is a mindset.

descriptive research

Vikas Mittal

BACKGROUND

What is descriptive research? A survey of marketing-research textbooks shows there is no single definition of descriptive research. Some authors, for instance, argue that only cross-sectional research is descriptive research, separating it from longitudinal studies. Others exclude qualitative research from descriptive research. Contrary to this limited and limiting view, we believe that descriptive research refers to a broad category of marketing-research studies that are used to “describe” a state-of-affairs, phenomenon, and/or trend for the firm. As long as the primary goal of the research is to describe rather than assert true causality in an experimental sense, we view it as belonging under the broad umbrella of descriptive research.

Most descriptive studies in marketing research are typically cross sectional in nature, though they also include longitudinal studies, tracking studies, and, in some cases, qualitative studies. In summary, descriptive research conceptualized most broadly is all manner of marketing research that is used to portray any phenomenon of interest. From a statistical analysis perspective, part of the portrayal includes not only different *levels* of various constructs and variables (i.e., univariate analysis) but also the *association* among them (i.e., bivariate and multivariate analysis). Consider the following examples of descriptive research:

- To ascertain its brand image, a firm does a cross-sectional survey of customers of its own brands and competitors’ brands on various dimensions. These results are then presented in the form of a perceptual map to the management.
- As part of its attempt to segment its customer base, a firm conducts a *cross-sectional* survey of its customers and potential customers. The survey data are merged with behavioral variables (e.g., television viewing habits). A cluster analysis is done to identify segments. The resulting segments are described

based on brand perceptions and attitudes, behavioral intentions, and other descriptive variables.

- To ascertain factors driving sales, a business-to-business firm measures product attributes, perceptions of sales-force responsiveness, and pricing policy. A regression analysis is used to identify the key drivers of sales.
- Automotive firms use *syndicated research* sources such as J.D. Power and Associates to monitor customer satisfaction, TGW (things gone wrong), and reliability of their brand.
- Sales trends of consumer packaged goods are tracked by brand, category, and market from syndicated *longitudinal* data provided by firms such as Neilsen.
- To quickly ascertain the impact of changes made to its check-in system, a hospital conducts a focus group of recently admitted patients. Feedback from this *qualitative research* is used to tweak and refine the system for improvements.
- A survey of students at a university shows high levels of dissatisfaction with the student center. A series of focus groups are convened to identify specific areas of improvement.

All of these are examples of descriptive research. The primary focus of this article is on cross-sectional research, though we do touch on other forms of descriptive research as well.

CROSS-SECTIONAL DESCRIPTIVE RESEARCH

Cross sectional, descriptive research is best described as a research study that aims to take a snapshot of the market place. In a cross-sectional marketing-research study, customers are surveyed at *one point in time*. On the basis of their responses to the survey, a set of conclusions that “describe” the phenomenon of interest can be drawn. There is a large variety of cross sectional, descriptive studies in marketing research (see SURVEY RESEARCH). Some important types of marketing-research studies using a cross-sectional design are described below:

1. *Buyer-behavior study*: In this type of a descriptive study, the firm wants to

2 descriptive research

describe various behaviors among its customers. These behaviors are not only those affecting the firms' brand directly, but also include any and every behavior that may be of interest (e.g., media-viewing habits, or behaviors involving competitor brands). Typical questions may include the following:

- a. How do customers use our (and competitor) brands after buying them?
- b. Where do customers go to purchase the brand they chose?
- c. Are there differences in brand usage patterns between newly acquired customers versus loyal customers?
- d. What are the different occasions for which customers use our brand (versus others)?

Then, different segments of customers are profiled and compared on the basis of a variety of behaviors. Notably, in many cases, these are self-reported behaviors.

2. *Brand perception study*: In this type of research, firms want to know how their brand is perceived by customers relative to other brands in the market place. Using a variety of rating scales, a single respondent may rate different brands on a variety of attributes. These can relate to brand attributes (e.g., brand personality) or product attributes, or a combination. The results of the study are visually depicted as a series of simple bar charts or, in some cases, a perceptual map created using a factor analysis or correspondence analysis. These positioning maps are used to identify the brand's position, vis-à-vis competitors, and among customers belonging to different segments.
3. *Customer segmentation study*: In this type of descriptive research, the goal is to obtain a random sample of all customers (current and potential) and measure variables, including psychographics, brand perceptions, demographics, usage, and so forth. Statistical techniques like cluster analysis can be used to divide the sample into segments. On the basis of the firm's objectives, the segments may be based on attitudes, perceptions, behaviors, or demographics (exclusively or some combination

of these). Once the segments are profiled, they help the firm to understand the market, decide on the target segment(s), and devise a positioning strategy. Segmentation studies are most useful for firms trying to get a fine-grained description of the market. In many instances, firms may conduct a descriptive study that combines elements of all the three types of studies described. Thus, combining a brand perception and segmentation study can reveal the brand's positioning among a variety of segments. Later these segments can be profiled on the basis of specific behaviors to help with targeting.

4. *Customer satisfaction study*: Firms will typically survey a cross section of their customers to measure overall satisfaction, behavioral intentions, and attribute-performance perceptions. On the basis of a customer satisfaction study, the firm can gauge the level of satisfaction among customers, how they perceive the performance of the firm on various attributes, and their likelihood to repurchase from the firm. The firm can also ascertain attribute importance, or the extent to which an attribute affects the overall satisfaction. Results of these studies help firms to create importance-performance charts that guide resource allocation for customer satisfaction improvement.
5. *Lost-customer study*: Realizing the high cost of customer acquisition, many firms now want to understand reasons for which customers may have stopped doing business with them. In addition to measuring customer perceptions of their own brand, a lost-customer survey also measures perceptions of the brand to which customers switched. Critical incident information, for example, a short description of a particularly dissatisfying experience, is also obtained. Results can be used to create strategies to reclaim lost customers as well as to prevent customer loss. Some of these studies also help firms to identify service recovery strategies.
6. *Advertising evaluation study*: To evaluate its advertisements, firms often conduct advertising evaluation studies. Typically,

these are before and after studies, using a pseudo-experimental design. A random sample of customers is surveyed about firm perceptions before an ad is run in the market. After some time (typically, one to three weeks) of the ad being run, another random sample of customers is surveyed. The before and after samples can be compared to ascertain the difference in perceptions among consumers. Such studies lack internal validity and cannot be used to infer true causality. Yet, they provide firms with a quick reading of the ad's effectiveness.

7. *Employee attitude and satisfaction study:* Though mostly used by HR departments, experience shows that marketing-research departments typically take the lead in conducting employee satisfaction surveys. Furthermore, in service firms, these surveys are also used to assess the impact of employee satisfaction on customer satisfaction. Typically, a small sample of employees at each sub unit (e.g., bank branch, retail outlet, or dealership) fill out a survey that measures overall job satisfaction and its antecedents such as satisfaction with supervisor, pay, organizational processes, and so forth. In addition, these surveys can also be used to identify training and employee development needs. Sometimes, they are also used to measure perceptions of the corporate brand among employees.

As mentioned earlier, this is not an exhaustive list of descriptive studies using a cross-sectional survey. Rather, it illustrates the broad spectrum of goals that can be accomplished using cross-sectional market-research studies.

Survey methodology for cross-sectional studies. A variety of choices are available including, in-person surveys, telephone surveys, Internet-based surveys, and mail surveys. The choice of a survey methodology is based on several criteria including the following

- *Cost:* The total cost of conducting the survey. In-person surveys are more expensive than phone surveys, because the

interviewer must travel to the respondent or vice versa. Typically, phone surveys are more expensive than mail and web-based surveys.

- *Speed:* In-person surveys can slow the data collection process because of travel time. Mail surveys, are somewhat faster, but telephone and Internet-based surveys are the fastest.
- *Versatility:* Mail surveys and Internet-based surveys allow respondents to evaluate visual stimuli (e.g., rate the different shapes or colors of a product or brand logo). On the other hand, telephone surveys and in-person surveys allow the interviewer to follow up and clarify the responses provided. Telephone surveys and Internet-based surveys also enable researchers to program complex skip patterns (respondents can be directed to different subsequent questions based on their answer to the present question), which is a weakness of mail surveys. Thus, each methodology is versatile in different ways.
- *Privacy:* Mail and Internet surveys afford the maximum privacy to respondents who can answer the questions in their homes. This is particularly important when studying sensitive topics or subject matters that elicit strong socially desirable responses. Telephone and in-person surveys afford relatively less privacy.
- *Cultural sensitivity:* When conducting surveys, attention should be paid to the local context. For instance, India and Mexico have relatively underdeveloped telephone service, and the mail is unreliable. Thus, it is more useful to conduct in-person surveys.

Many other factors besides these should be considered when making the choice of a survey methodology. More and more, companies are opting to use Internet-based surveys as they provide the speed of a telephone survey as well as the visual elements of a mail survey. However, Internet surveys rely on email lists that may be substantially biased on the basis of computer ownership and/or access. Still, with increasing Internet access this may be less of an issue.

Sample design for cross-sectional studies. The external validity, that is, the extent to which

results can be generalized to a particular population, of a cross-sectional survey critically depends on the quality of the sample chosen. Theoretically, the best sample is one where the units included in the sample are randomly chosen from the population of interest. However, in reality, all units of the population are not available for potential inclusion, as the random selection is done from a sampling frame, or a list of all available population units (see SAMPLING TECHNIQUES; PROBABILITY SAMPLING). For instance, a firm wanting to create a random sample of its customers may choose to select customers from its email database. To the extent that some customers simply do not have emails, they will be underrepresented in the sampling frame causing the final sample to be *underadjusted* for those of the firm's customers who do not have emails. It may also be that some of the people whose email addresses are in the list are no longer with the firm. In this situation, the sampling frame will be *overadjusted* for noncustomers. Thus, because of underadjustment of the sampling frame some units who should be part of the random sample are not, and because of overadjustment some units who should not be part of the random sample are included. If these two subsets are systematically different, then the ultimate random sample can be biased. For instance, consider a local bank in Houston. Many of its ultrawealthy clients do not provide an email address, and many student clients whose address the bank has have migrated to other cities. Given this, any random sample drawn from its email list will be biased in representing the firms "current customer base." Thus, when creating a random sample, biases because of the composition of the sampling frame should be explicitly noted.

The marketing-research manager should also carefully consider the decision about the desired sample size. Clearly, a larger sample is desirable as it reduces the sampling error, that is, the margin of error (at a given level of confidence, say 95%) associated with the study. However, for a given budget, increasing the sample size also increases the nonsampling error because of nonresponse bias and administrative errors. In many situations, nonrespondents are systematically different from those responding to the

survey. Thus, even with a large sample size, a high nonresponse bias can seriously undermine the representativeness of a study. The best strategy is to have a smaller sample size, but use the available budget to increase the response rate. This will ensure that all the units randomly selected from the sampling frame for study inclusion are, in fact, part of the study. In many cases, the length of the survey and the design of a survey (e.g., uncluttered survey with lots of white space) can significantly impact the response rate. For instance, longer surveys not only decrease response rate (thereby requiring a larger sample to obtain a prespecified number of completes) but also necessitate higher respondent incentives.

Constructs measured in cross-sectional descriptive studies. The constructs measured in a descriptive survey consists mainly of self-reports on a variety of domains including customer perceptions, attitudes, intentions, behaviors, and background variables. Broadly speaking, they may be classified in the following categories (see QUESTIONNAIRE DESIGN).

- *Brand perceptions and attitudes:* Customers have perceptions of and attitude toward a brand or a firm. For instance, scholars have shown that a positive brand attitude helps a firm to insulate its sales in case of a negative crisis. In a typical cross-sectional study, brand perceptions and attitudes can be measured using Likert or Semantic differential scales. Examples are as follows:
 - How would you rate Money Bank on the following dimensions:
 - Safe–Unsafe; Friendly Staff–Unfriendly Staff
 - Rate your agreement with each statement:
 - My assets are safe at Money Bank (1 = strongly disagree, 10 = strongly agree)
 - The staff at Money Bank is friendly and courteous (1 = strongly disagree, 10 = strongly agree)
- *Behavioral intentions:* Scales with end points such as "extremely likely" and "extremely unlikely" are used to measure various intentions such as intent to purchase a brand,

intent to repurchase a brand, intent to engage in word of mouth, and intent to recommend. Typically, these intention variables are used as surrogates of actual behavior. However, though positively correlated, the strength of the relationship between attitudes and behaviors varies widely. Thus, the presence of high intention scores should not be interpreted as correspondingly high behavior among customers.

- *Stated behavior:* Surveys also ask consumers to retrospectively state a variety of behaviors. For instance:
 - In the past six months, how often have you visited a Greenery grocery store?
 - What percentage of your disposable assets is invested with firm X and what percentage with firm Y?
 - In the past months, to how many people have you recommended Brand Y?

Despite their limitation of one-to-one correspondence with actual behavior, stated behaviors are used extensively to understand customer behaviors.

- *Demographics:* Customers typically fill out a background section measuring demographics such as gender, race, income, marital status, and so forth. These are used as classification variables in the analysis.

The above is a list of the major categories of variables measured in cross-sectional descriptive studies. Note that the specific variables measured depend on the needs of the firm.

Analysis of cross-sectional descriptive data. Typically, descriptive cross-sectional studies are analyzed using a variety of analyses. An overview is provided in this section.

Univariate analysis. In univariate analysis, the goal is to describe each variable one at a time. This can be done using either frequency counts (or percentages) or averages. Consider the variable, “My assets are safe at Money Bank,” which is rated on a 10-point scale (1 = strongly disagree, 10 = strongly agree). The analyst may calculate the average score on this variable, say 7.5. Using percentages, the analyst may report the top-2 box score (percentage of people giving a rating of 10/9), say 82%. Depending on the

firm’s needs, the analyst may report top box scores (percentage of people giving a rating of 10), or top-3 box score (percentage of people giving ratings of 10/9/8), or any top- X box score. Typically, the average score and the top- X box score are positively correlated though the magnitude of the correlation depends on the distribution of the scores across respondents.

In a marketing-research report, the average scores or top- X box scores are reported as simple tables or bar charts. To this end, the analysis can usually be conducted using a spreadsheet or a basic statistical analysis package. Despite the simplicity, the analysis is useful in many respects. It provides a quick snapshot of all variables in the survey. In many marketing-research situations, this is all that a manager needs to draw conclusions or conduct basic hypothesis testing. For instance, on the basis of the observed top-2 box score of 82%, the manager can statistically test the hypothesis that in the population of interest the top-2 box score is 75%.

Bivariate analysis using cross tabulations. The goal of bivariate analysis is to analyze two variables at a time. In most marketing-research studies this is done using two-way cross tabulations, known as *tabs* (see CROSS-TABULATION). For any given study, the client and the marketing-research firm decide on the format of the tabs. The most important decision is to agree on the banner and the stub. The banner of a cross tab represents the column variables and typically consist of segmentation variable(s) by which the data is broken down. The stubs are the rows, and consist of the variables that are expected to vary by the segments, or by the banner.

For the variable, “My assets are safe at Money Bank,” which is rated on a 10-point scale (1 = strongly disagree, 10 = strongly agree), suppose the desired banners are gender, income, and customer status each having the following categories:

- Gender (male/female)
- Income (high, medium, low)
- Customer status (current customer/non-customer).

It should be obvious that these three banner variables lead to a total of seven banner points

Table 1 A cross table showing banner points and stubs.

| | <i>Gender</i> | | <i>Income</i> | | | <i>Customer Status</i> | |
|---------------------|---------------|---------------|---------------|---------------|------------|------------------------|--------------------|
| | <i>Male</i> | <i>Female</i> | <i>High</i> | <i>Medium</i> | <i>Low</i> | <i>Current</i> | <i>Noncustomer</i> |
| Top-2 box score (%) | 80 | 75 | 70 | 90 | X | 90 | Y |

(2 + 3 + 2). Using these banner points, the cross tables describe the percentage of people who fall in each category of the questions analyzed in the stub. For instance, the top-2 box score for Gender may be displayed as in Table 1.

The rows can be as detailed or as aggregated as desired. For instance, the cross tabulation can show the number and percentage of people giving each rating on the 10-point scale, for a total of 10 stubs. Additionally, the cross tables can also report the average, and the top-*X* box scores. Thus, for a 10-point scale-item, one can have more than 10 stubs.

When preparing a market-research report, it is customary to display these data in the form of bar charts, with different colored bars representing each banner-point. Such bar charts are simple to create and visually easy to understand. This simplicity, as explained earlier, and the associated speed, is an important reason for the widespread popularity of cross tabulations. From a statistical analysis perspective, cross tabulations allow people to test hypotheses about the independence of two categorical variables using the chi-square test. They can also be used to compare the means (*z*-test or *t*-test for means) or percentages (*z*-test for proportions) based on two groups. Such hypothesis testing enables the manager to compare how two groups are different with respect to a focal variable.

Multivariate analysis of cross-sectional data. In many cases, multivariate techniques are used to analyze cross-sectional data for descriptive studies. A complete discussion is beyond the scope of this article, though a brief overview with examples is provided.

- *Perceptual mapping:* One set of multivariate techniques such as factor analysis and correspondence analysis is simply used to characterize respondent perceptions in a visually meaningful way. Thus, perceptual maps

are created from ratings of multiple brands provided by the customers. Perceptual maps provide a visual representation of various attributes and brands to identify the underlying patterns in their interdependence.

- *Cluster analysis:* This analysis classifies the respondents in the dataset based on their similarity on some prespecified criteria (e.g., attribute ratings) (see CLUSTER ANALYSIS). The most common clustering technique used to accomplish this in marketing research is called *k-means clustering*, though advanced techniques such as latent segmentation are also employed.
- *Multiple regression analysis:* In this technique, a set of *independent* variables is used to predict a *dependent* variable (see MULTIPLE REGRESSION). For instance, overall brand attitude is predicted on the basis of specific brand perceptions of “exciting,” “dependable,” and “novel.” Or, customer-share of wallet may be predicted on the basis of their satisfaction with the firm’s service, brand commitment, and household income. It should be noted that even though there is a dependent variable in regression analysis, the analysis makes no presumption about causality—that is, the independent variables are simply associated with the dependent variable, rather than causing it in an experimental sense.

Limitations of cross-sectional analysis. A key limitation of cross-sectional research is its inability to provide causal conclusions. In other words, all variables are simultaneously measured in a single point in time, and thus, temporal sequencing—a precondition for establishing causality—is missing. Nonetheless, in most cases, managers use their mental models to impose causal ordering on the variables measured in the survey. For instance, based on

their experience, and causal research conducted in the past, the managers may have a mental model of causality that an increase in promotion through coupons causes unit sales to increase. From this mental model, a manager may feel comfortable interpreting the cross-sectional results of a correlation between the amount of promotion and unit sales in a “causal” sense. Clearly, the magnitude of the association may still be inflated owing to common methods bias inherent in cross-section research.

Another limitation of cross-sectional research is that it does not allow one to observe changes within a unit. Thus, a person’s perceptions of a brand may change over time. However, if we happen to measure it at a time when they are high (e.g., right after an advertising campaign) and we mistakenly conclude such perceptions are stable, we may describe them as being “high” even after some time has lapsed. In reality, the perceptions may have declined after a period of time, leading to an incorrect conclusion.

Conclusion. It should be apparent to the reader that descriptive research using a cross-sectional design incorporates many elements about which decisions need to be made. Each decision has a critical impact on the survey outcome, and the nature and type of conclusions that can be drawn from the study. Thus, it is advisable to obtain guidance from marketing-research experts when designing the study, particularly in regard to elements like sample design, survey design, and analysis plan. Some sources for guidance include Alreck and Settle (2004), Parasuraman, Grewal, and Krishnan (2007), and Salant and Dillman (1994).

LONGITUDINAL DESCRIPTIVE RESEARCH

In contrast to a cross-sectional study, which is best described as a *snapshot*, a longitudinal study is like a *movie*. In a longitudinal study, data from the same entity is gathered over multiple periods of time. For instance, the same customers may be interviewed each month to obtain data on what groceries they purchased each month and their spending patterns. An automotive buyer may be surveyed within two weeks of buying a new car, after six months of ownership, and

then again after three years of ownership. By interviewing the same entity over time, the researcher can draw conclusions about changes in the *levels* of variables of interest. The ability to observe changes in the variable of interest is a key benefit of longitudinal research as compared to a cross-sectional study.

In most research settings, interviewing the same-people by tracking them over time can be expensive and time consuming. Even if the firm has the necessary financial resources and time to devote to a longitudinal study, several problems may beset such a study. First, respondents may drop out of the study for reasons that are beyond the control of the firm. These may range from mortality to relocation to simply fatigue from repeated participation. Second, there may be sensitization and measurement reactivity. In other words, when the respondent is filling out the same survey again and again, the mere act of doing so can sensitize respondents and change their responses. Using a within-subjects analysis or a repeated-measures analysis can mitigate this concern to some extent.

Relative to cross-sectional studies, longitudinal studies are less often used in the marketing-research industry. This is not a limitation of longitudinal studies, but may merely reflect the desire for cost-effective ways of addressing marketing-research needs. It should be noted that longitudinal studies lend themselves to statistical analysis that enables stronger causal conclusions and allows researchers to control for unobserved heterogeneity.

TRACKING STUDIES

A tracking study is different from a longitudinal study described above. In a longitudinal study, the same entity (e.g., customer) is surveyed or observed over different time periods. Thus, in a longitudinal study, the same customer would provide data over several time periods. While such a longitudinal study could well be a tracking study, the typical tracking study in marketing research is based on aggregating data from cross-sectional studies over time. For example, a firm may conduct a cross-sectional survey of customers who visit its store in Ohio every quarter to gauge brand perceptions. A similar survey, for the sake of example, is also done

8 descriptive research

on behalf of its store in Texas. In other words, a random sample of customers in Ohio and Texas is interviewed every quarter. Suppose for the Ohio store, the scores for seven consecutive quarters are 5.4, 6.5, 7.1, 7.4, 7.9, 7.8, 7.9 (perceptions measured on a 10-point scale). Similarly, suppose the scores for the Texas store are 9.5, 9.5, 9.1, 8.9, 7.5, 6.1, 6.4. These scores, which comprise the data for the tracking study, have several properties:

- They are based on cross-sectional surveys of customers at each store. Thus, the tracking study is not a longitudinal study at the customer level: every quarter a new cross-sectional sample of customers is surveyed. In other words, it is not the same customer who is followed up over seven quarters. Rather, results from seven separate cross-sectional surveys are averaged and used to monitor a trend over time.
- The average scores at the store level are “tracked” over time, and treated as having longitudinal properties. Thus, by aggregating (e.g., averaging) cross-sectional data from individuals over time, a longitudinal time series can be created at a more aggregate level of analysis (i.e., the store) to which the individual contributing the cross-sectional data belongs.
- Several examples of such tracking database can be found. The American Customer Satisfaction Index creates a satisfaction score for each firm on the basis of a cross-sectional survey. The scores for each firm are tracked over time, and treated as having longitudinal properties. Consider the Consumer Confidence Index. It is based on a cross-sectional sample of consumers every period. However, aggregated for the entire United States, the index is treated as a longitudinal variable. For an individual firm, examples of variables that may be tracked over time include
 - top- X box scores on variables like satisfaction, brand perceptions, and repurchase intentions;
 - average ratings on attitude, perception, and intention variables;
 - percentage of people engaging in a certain behavior over time (e.g.,

percentage of people complaining, or calling customer service);

- indexes such as net promoter score.

QUALITATIVE DESCRIPTIVE RESEARCH

Descriptive research can also be classified on the basis of whether it is qualitative or quantitative research. The preceding sections of this article have focused on quantitative descriptive research. A key feature of quantitative research is that the data collected for such research is typically collected in a structured manner from a relatively large sample of customers. Qualitative research, on the other hand, primarily relies on unstructured data gathering that is designed to gain insight into the “why” and “how” of various phenomenon.

In most marketing-research applications, qualitative research takes the form of focus groups or in-depth interviews conducted with key informants chosen on the basis of the researcher’s judgment. Different from observational research (e.g., ethnography), focus groups and in-depth interviews rely on people’s ability to verbalize their thoughts and feelings about the topic at hand. Because this is a relatively difficult task, a trained moderator or interviewer guides the participant using questions, probes, and other facilitating techniques to elicit information. For example:

- A health maintenance organization (HMO) conducted a survey and found that 75% of its members wanted the physician to “treat me with respect.” However, it was not clear to the HMO what specific actions physicians could take to convey respect. To this end, a series of focus groups were conducted to elicit specific encounters that were perceived as respectful and/or disrespectful and why.
- A Montessori school wanted to conduct a survey and find out how people view Montessori education as different from a traditional education. However, there was no battery of items that could be used in the survey. Qualitative research was used to understand people’s perceptions of and attitude toward a Montessori education, and from there survey items were developed.

The first example should, at least, illustrate that qualitative research is not always a precursor to quantitative research. It is true that in a majority of the cases qualitative research is used to help researchers understand the phenomenon in question, and aid in designing the quantitative survey. In some cases, however, qualitative research has been finding its use as a back-end clarification and amplification tool designed to help researchers interpret findings from quantitative studies. In many cases, we find that supplementing quantitative research with qualitative research can improve the descriptive power and insights manifold.

CONCLUSION

It should be evident to the reader that the term *descriptive research* is descriptively simple but deceptively simplistic. It applies to a very broad range of studies, and descriptive studies can be classified in many categories. For instance, they may be classified as qualitative or quantitative descriptive research. They can be classified as cross-sectional or longitudinal descriptive research. They may be classified on the basis of the substantive nature of the study into buyer-behavior studies, brand perception studies, customer segmentation studies, or customer satisfaction studies. Descriptive research also includes syndicated studies. Among all the quantitative studies, cross-sectional surveys, and the resulting tracking study, remain the most widely used descriptive research.

Looking to the future, we expect wider use of longitudinal studies. Changes in information technology have allowed firms to monitor and track consumer behaviors in ways that are relatively unobtrusive. They also allow firms to administer surveys in ways that are more cost effective. Thus, we should see a gradual uptake in the use of longitudinal studies. We also expect more use of multivariate data analysis techniques. Software packages such as SPSS and SAS have allowed users to conduct these analyses with relative ease. In using these software packages, dangers associated with “little knowledge” should be acknowledged. We have seen many instances where multivariate analysis was conducted simply because it could be done, or cases where knowledge of the software was confused with a mastery of the statistical technique. Finally, we expect firms to be using various forms of descriptive research in a more integrative manner. The divide between qualitative and quantitative research, especially, should be bridged to gain richer insights that also have high levels of external validity.

ethics in marketing research

Marcus J. Schmidt

In recent decades there has been a growing trend to base strategic marketing decisions on market research data. The periodic survey of marketing research sponsored by the American Marketing Association (AMA) investigates the vast application of marketing research techniques in American businesses. When comparing results of 1988 and 1997, it turns out that the use of research methods activities has increased within 28 out of 34 categories (test marketing, consumer satisfaction studies, etc.). A study carried out by a Danish market research agency (Jysk Analyse) several times between 1984 and 2007 shows a similar trend. While no definite estimates exist, it appears that companies' financial resources invested in marketing research on average have gone up during the last decades. The growing use of marketing research studies by companies and public authorities has resulted in an increased focus on ethics in marketing research.

DEFINITION

Marketing research ethics derive from a marketing researcher's relations with the parties in the research process, including respondents, interviewers, the research firm, clients, and the general public. A researcher has the responsibility to treat respondents fairly by being truthful to them about the nature and purpose of the research. At the same time, he or she has the responsibility to gather accurate and reliable data for the client. Whenever the fulfillment of these responsibilities creates a conflict, a research ethics problem arises. Unethical behavior is a form of misconduct that appears if those involved in the research process violate proper marketing research principles (Akaah, 1990).

Figure 1 provides an overview of the key elements involved in a marketing research process.

All elements may cause ethical problems or dilemmas:

Respondents now and then provide answers knowing that they are incorrect. For instance, the person may underreport his or her

consumption of alcohol or overreport purchase of fruits because drinking too much is regarded unhealthy and thus socially undesirable, whereas eating fruits is regarded healthy and therefore considered socially acceptable. The issue of *social desirability* is addressed in another article in this encyclopedia (see SOCIAL DESIRABILITY BIAS). While a respondent's refusal to provide a correct answer cannot be regarded unethical, it may be inappropriate to deliver results to the client or to publish findings without mentioning the possible bias.

The *questionnaire* may contain questions that do not interest the respondent. Thus he or she will be less involved in filling in the answers. Also, the questionnaire may address sensitive topics: questions about sexual behavior, usage of drugs, religious beliefs, political preferences, and so on. It is known from research that sensitive questions often result in invalid answers.

Questions may be formulated in such a way that responses serve the interests of the client.

A private company obtained a license from the government to exploit a country's subsoil for 99 years. The company was allowed to drill for oil and sell it by paying an annual fee to the government. Once large oilfields were found and the company's profits began to swell, some politicians and experts began arguing that the contract was too attractive to the company and that the government needed to renegotiate it.

The editors of newspaper A were in favor of a renegotiation. They had an agency asking a random sample of respondents the following question:

The government has given private company X a monopoly on drilling oil in country Y's subsoil. Members of parliament now discuss the possibility of an expropriation – a statutory confiscation entailing economic compensation. If the proposal is adopted other companies – private as well as state-owned – are allowed to drill for oil along with company X. Are you in favor of or do you oppose this?

Soon afterward, newspaper B – being against the renegotiation – had another agency ask *its* random sample of respondents:

The parliament must soon decide upon a bill implying that the government breaks its

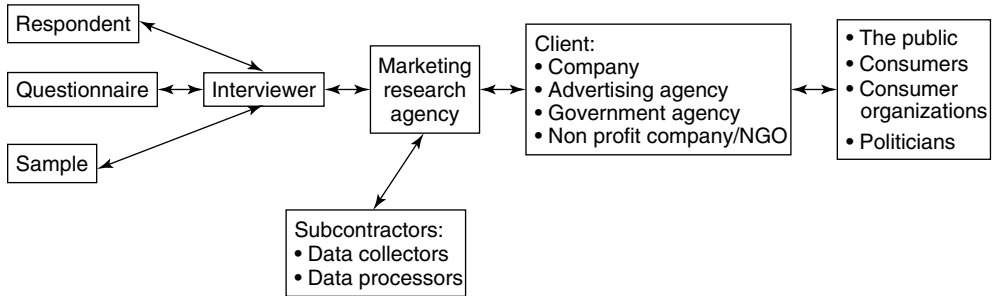

Figure 1 Potential ethical issues.

agreement with company X about drilling. What do you think: Should the government comply with the agreement or do you find it acceptable that the government breaks the agreement? (OK/Not OK for the government to break agreement).

It is of little surprise that a majority answered “in favor” to the first question while a majority answered “not OK” to the latter question. Notice that in the present example – especially in the first case – it is not the question as such that causes a problem. The problem is that respondents are given “a helping hand” with regard to how the critical terms included in the text are to be understood.

In the former case, we are informed that an expropriation is in accordance with the law and that an economic compensation is being paid. Moreover, a monopoly business is transformed into a business with competition. In the second case, it is stated that passing the bill implies that the government breaks an agreement. For many people, a monopoly is associated with negative values (high prices, little product development, low service, big profit), whereas competition is regarded positively because of the opposite arguments. At the same time, it is broadly expected of a democratically elected government to comply with laws and agreements it has signed.

Both questions violate an ethical principle of avoiding leading formulations. (Both surveys were conducted by subsidiaries of renowned international marketing research agencies). An interesting observation: It turned out that the CEO of the oil-drilling company was a member of the board of directors of newspaper B. Also the top manager of the agency doing the study

for newspaper B was a close personal friend of the newspaper’s editors.

A careful researcher should spend sufficient time designing a questionnaire (see also Sudman, Bradburn, and Wansink (2004)).

The *sampling frame* may favor the interests of the client: Two competing trade magazines were eager to inform readers that *their* magazine was the preferred source of information among business managers and thus the most cost-effective medium for placing advertisements. Magazine A’s core readers were known to be mostly small companies while magazine B’s core readers were primarily middle-sized and big companies. Magazine A asked its market research agency to base the sample frame on small companies, whereas magazine B asked its agency to concentrate on middle-sized and big companies. It turned out that the overlap of sampling frame was as low as 5%. Consequently, based on their respective samples, both magazines could announce publicly that they were the preferred magazine among business decision makers.

The researcher should aim at selecting the most valid and reliable sample given the research problem at hand and not one that best serves his or her own interest.

The *interviewer* may bias results in several ways (see Table 1).

Subcontractors. Use of data collectors and data processors incurs additional problems. Each supplementary external element that is added to the research process enhances the risk of bias and of ethical problems. Data collectors may miscomprehend the sampling frame or they may be unable to fulfill sample quotas (i.e., that at

Table 1 Systematic interviewer bias.

|---|
| <p>In 1994, a German interviewer, Heiner Dorroch, published a biographical book, based on his life as a very “productive” interviewer for several big market research companies (Dorroch, 1994). According to Dorroch, interviewers are badly paid and therefore they are pressurized into faking interviews in different ways: often questionnaires used for personal interviews contain 500 questions or more (!)</p> <p>Being aware of the challenges that long interviews cause for interviewers, research agencies have developed quality control procedures. For instance, the agency phones a sample of respondents (i.e., 10% of the sample) and asks them if they have indeed been visited by the specified interviewer on a given day. Since Dorroch had himself been involved in designing control checking procedures he knew exactly how to circumvent them. He comprehended that controllers would ask if he had been visiting a respondent’s address. Also, he realized that they would confront the respondent with a few control questions: Did the interviewer ask the respondent to rate advertisements? Was the respondent exposed to a blind test of three cheeses, and so on. However, what the controllers did not check was <i>the length</i> of the interview and the number of questions asked. So, Dorroch was able to cut down the interview to about 20% of the intended length. Afterward he would fill in the missing answers by himself. Provided that a respondent favored ecological views during introductory screening questions, Dorroch assumed that that the person would purchase more ecological products and that he would possess more critical views regarding a company’s social responsibilities than the average respondent and so on.</p> <p>When interviewing managers, he frequently experienced that the interview was interrupted because the manager was too busy to complete the interview. In such cases, it became common to have another manager continue and complete the same questionnaire. Dorroch managed to work for several marketing research companies at the same time. So, during an interview, he would confront the respondent with questionnaires for several agencies. When he was fired at one agency he continued working for the same agency as a subcontractor for another interviewer. Dorroch also reports about a survey for a construction company where the payment of interviewers was directly associated with the number of confirmative responses: the more respondents that reported to be unsatisfied with their present apartment, the higher the payment to the interviewer and the more orders the client could expect to get from government authorities. As a consequence, the estimated need for reconstruction of apartments was significantly overestimated.</p> <p>According to Dorroch, it is a major problem that interviewers are paid per completed interview. And because of the low earning per interview, only a very productive interviewer is paid an amount of money that compares to that of an average industrial worker. Dorroch claims that the procedures described in his book are more or less standard practice among interviewers.</p> |
|---|

least 80% of households own a DVD-recorder), while data processors may compromise on data quality checks or may use inappropriate weighting procedures.

*The marketing research agency*¹. Problems attributed to employing a subcontractor also apply to the agency if the activity is carried out internally rather than being outsourced or offshored.

Sometimes, marketing research companies have been accused of reporting unrealistic return rates. In a pan-European study conducted by an

international agency, it turned out that response rates were around 90% in a South European country while it was only 40–50% in Scandinavian countries – although the contact method was the same (telephone). Did the subsidiary with the 90% rate only count interrupted interviews as nonresponse but not missed calls and refusals? In the present case, the subsidiary was not at all cooperative regarding specifics about the details.

Owing to different reasons, agencies frequently refuse to unravel details about a research study it has conducted:

4 ethics in marketing research

1. Doing so might give competitors access to confidential information about the client.
2. The research model is unique and is not to be disclosed to outsiders.
3. Giving access to details violates the anonymity of respondents.

Assume that an independent researcher learns about a study, say, at a seminar or in the trade press. He or she wonders about the results and finds them to be strange, confusing, or not in accordance with what he or she would expect. Therefore, he or she would like to check the validity of the research study. However, owing to one or several of the above reasons, the agency refuses to provide the necessary details about the study. In this case, it might be regarded unethical *not* to provide the researcher with technical details. On the other hand, providing details to the researcher may *also* be regarded as unethical: First, handing over the relevant information to the researcher may be regarded unfair to the client. Second, it may provide outsiders and thus competitors with access to the research agency's toolbox ("magic formula" or "secret recipe") and third, respondents may feel that the agency violates their integrity and anonymity. To sum up, this is a typical example of a clash of conflict between: (i) transparency of research and (ii) confidentiality.

Many marketing research agencies today use branding for protecting their product offerings. For instance, a consumer products company wanting to analyze the loyalty of its customer base can choose from among *Loyalty Plus*® from GfK, *Conversion Model*™ from TNS Gallup, and *BASES*® from Nielsen – just to mention one product from three different research suppliers. The common denominator of such branded products is that they are proprietary services, which means that the supplier refuses to disclose exactly how the research is conducted, which buyer-probability algorithm is employed, how the model produces repeat purchase rates, and so on. The underlying rationale of branded products (also known as *black box branding*) is to charge a premium price for the product service. For the client, such branding has the disadvantage that it becomes very difficult to compare the validity and quality of alternative approaches and figure out which

one serves his or her interest best, given the specified price. While confidentiality with regard to branded models cannot be perceived as unethical, a common effort by the industry to establish a set of common ethical standards or principles for, say, conducting studies of consumer loyalty definitely would be helpful to clients.

The client. According to most textbooks, the client is a private company. But sometimes, the agency's contact is a subcontractor of the client company, that is, an advertising agency. In other cases, the client may be a government agency, a nongovernmental organization NGO or even a political party. The way a client treats results obtained from the research agency involves a lot of latent ethical problems. The client may have a hidden agenda and provide the agency with "appropriate" input with regard to the questionnaire, sample, which variables to use (and which not), and which research finding to report.

Why should a client want to influence the research process? In a private firm, there may be opposing interests within the management: The financial manager wants to cut costs and does not wish to spend money on a new product, whereas the marketing manager thinks that a new product is needed because the company is losing market share to its competitor. The marketing manager commissions an agency to carry out a research study. Clearly, he or she is interested in results that are supportive to his or her agenda: should the research design begin with a screening interview where only consumers who show positive interest toward the new-product concept are asked to participate in the focus group or in the market test? No doubt this would bias results yielding higher acceptance rates and purchase probabilities compared to a true random sample.

While the marketing manager's behavior represents an act of misconduct in a company context, it does not directly affect companies or persons outside the company.

But, suppose that the marketing manager willingly misrepresents or manipulates a customer satisfaction study, say, by merging the response category "don't know" with those being satisfied or by ignoring that the nonresponse category is overrepresented by former customers. Next presume that the satisfaction figures are used in

an advertisement (“88% of our customers are satisfied” – source: Agency XYZ). This would be an example of unethical behavior since it misrepresents the research carried out by the agency. Moreover, it deceives consumers by exposing them to information about the company that is not true (too optimistic).

It happens that the company’s management refuses to use or publish findings either because it does not believe in the findings or because it finds them politically incorrect. A businessman once hired a group of graduate students to carry out a study about the need for a new trotting track in the region where he lived. He was himself an enthusiastic believer in the trotting-track project. But since he needed to convince the municipality, supportive research findings were required for publication in the local press. After having conducted interviews with potential customers and experts, the students concluded that the probability that the trotting track would ever become profitable was almost zero. There were several successful competing tracks at a driving distance of within one hour. The competitors had big resources for marketing campaigns and for hiring the best jockeys and horses. Moreover, loyalty among visitors of the existing tracks was generally high: Very few of those being interviewed at competing tracks indicated an interest in shifting to the new intended track. The report obtained a top grade at the business school. However, when the businessman read the report he became very angry and even called the business school’s president complaining about the “negative” and “unproductive” report. The businessman decided not to publish any of the findings. Instead, he continued lobbying for the track (It was never built, though).

In the present case, we must regard the businessman’s behavior as unethical.

In the following section, we will look at some more relevant dilemmas in the marketing research process.

RESPONDENT – AGENCY DILEMMAS

Some examples causing ethical problems are as follows:

1. An agency sells the respondents’ names and demographic data to another company without their approval.
2. Respondents are contacted by a company whose purpose is to sell products. But the company disguises the true intention as an interview belonging to a survey (the contact form is sometimes called *sugging*).
3. Some persons choose not to have their phone number listed anywhere (secret numbers). Nevertheless, the number is randomly selected by a computer and the person is called by a research agency.
4. Respondents (i.e., employees of a super-market owned by the client) are contacted by the agency’s interviewers disguised as customers. The purpose is to assess how the respondents react to requests from customers. The procedure is known as *mystery shopping*.
5. An agency collects unobtrusive data from consumers who do not know that their behavior is being recorded – for example, assembling trash from households, carrying out interviews while using a hidden tape recorder, observing shoppers through a one-way mirror or letting respondents read a magazine that has previously been contaminated by a chemical liquid. An overview of *observation methods* is provided in elsewhere in this encyclopedia (see OBSERVATION METHODS).

The first two examples must be regarded unethical while the last three have been used by market researchers for many years.

Calling a person, who has done something actively for *not* being listed, causes an ethical dilemma. The person wishes only to be called by family and friends that have been provided the number but not by others like an interviewer or seller.

Several European consumer organizations have complained about calling unlisted numbers. Indeed, a market research company could contact the telephone company and get a file with the listed numbers. The sorted file could then be merged with a sorted file of the randomized numbers and only when there are duplicated numbers in a row the number may be called. Since all telephone companies must

6 ethics in marketing research

be contacted, the procedure is cumbersome but it can be handled. Several European research agencies are known to have used this procedure. A serious problem with this practice is that eliminating unlisted numbers threatens to bias results. In certain regions of some European countries, 30–40% of numbers – and especially new ones – are not listed. According to market research agencies females, singles, and widows are overrepresented among those having unlisted numbers.

Ideally, respondents should be informed about the study's purpose at the beginning of the data collection. Unfortunately, disguising the intention of a study is sometimes necessary for obtaining valid results. For instance, it does not make much sense to tell an employee in a supermarket at the first contact that the interviewer is a mystery shopper. This would render the research useless. In any case, the person whose behavior is under observation should be told about the study's true purpose immediately after the interview. And it should be possible for a respondent to have all available data (tape, video, written notes, etc.) withdrawn.

INTERVIEWER – AGENCY DILEMMAS

1. An agency is concerned about the performance of its telephone interviewers and conducts supervisory monitoring of their phone conversation with respondents.
2. A person applies for a job as interviewer at an agency and is hired for conducting in-home interviews. However, there is a hidden agenda: the person is employed by the secret service and by presenting himself as an interviewer of a respected and well-known agency, he obtains a unique opportunity of getting inside the apartment of persons being under surveillance for planning acts of terrorism. Notice that as long as the person does not reveal his true intention, the ethical problem concerns the interviewer. But if he reveals his true intentions while being hired, the problem is that of the agency.

Supervisory monitoring has been sharply criticized by Scandinavian organizations representing the interviewers' rights. A California law on eavesdropping, making it illegal to listen to

an extension, may restrict the use of supervisory monitoring (Malhotra, 2007, p. 213). As long as the secret service agent acts in accordance with the country's law (presuming it is a democracy), and the pretended activity has been sanctioned by a judge, the moral question does not arise or it is offset or overruled by considerations regarding the security of the state.

AGENCY – CLIENT DILEMMAS

1. A client obtains multiple bids for a project. Since several bids appear to be of similar quality, he or she chooses the cheapest one. The study is carried out by the agency and the report is sent to the client. When the client asks for a slideshow presentation by the consultant and for some supplementary cross tabulation, he or she is told that this was not included in the original price and therefore a surcharge is required because of the extra cost. The problem is known as *low-ball pricing*. A decent agency consultant should provide a detailed break-down of the price-estimate of different processes/elements of the research study (say, questionnaire design x Euro, field interviewing y Euro, basic report z Euro etc.). A sheet containing such economic specification should then be made available to the client before the study is carried out. In this way the client gets a better overview of the added cost, say of new data analyses, slide show presentations etc.
2. In an effort to reduce costs, questionnaires from several clients are bundled and data for all clients are collected during the same interview. This can be a cheap way for clients to get primary data that otherwise would be too expensive. The method is known as an *omnibus interview* or *piggybacking*. An ethical issue arises in a case where the client believes that his or her study is carried out separately and thus is getting all attention from respondents. Had the client been aware that his or her, say, 20 questions were part of a 500-question interview, he or she might fear that the quality of the study would suffer because of the respondents' information overload. Sometimes, an agency works

for two close competitors at the same time without informing them about it. Since they are within the same business, there is a good chance that both clients are handled by the same consultant. Often, a successful study necessitates that the clients reveal confidential information like marketing strategies and competitive information. He or she would *definitely* not like any of this information to somehow be disseminated to the competitor. But what if the consultant discloses restricted data on one competitor to the other, say, with the purpose of doing the client a favor and thus strengthening the relationship? Handing over information to a competitor, given this setting, is unethical. However, assume that a potential client is told that the agency currently is working for a competitor, but that the two companies will be served by different consultants. If the client, nevertheless, wants to place his or her order, an ethical problem does not exist (another option would be that the agency has a policy of not working for two competitors at the same time). A special case is that of *syndicated research* studies like household panel surveys, retail audits, and TV-meter analyses (*see* PURCHASE, SCANNER, AND MEDIA PANELS). Here the client knows that he or she would have to share sensitive market information with a competitor, provided the competitor is willing to pay for this information. For instance, if the client is a coffee producer who tracks the markets shares of its brand portfolio, then there is no way to prevent a competitor from getting access to the same information.

3. An agency discovers that one of its interviewers has been faking most of his interviews. The interviewer confesses and is fired (after consulting its lawyer, management decides not to take the case into court). As a matter of fact, the person was by far the most productive interviewer of the agency. With regard to several recent studies for important clients he had conducted 20–30% of all interviews. One study was the last pre-election poll widely published showing that the government would be defeated. The government lost by a very close margin. On the basis of another analysis, management,

after being much in doubt, decided not to launch the new product. Should the agency tell the clients that about one fourth of the data that were collected for the company are invalid? A decent manager would tell the clients what has happened, and maybe offer to conduct new interviews instead of using the faked ones, and make revised reruns for no charge. Also, clients could be offered a discount on new studies (however, the pre-election poll cannot be corrected!).

4. A food-processing company is about to launch a new product. So the marketing manager contacts the agency. His or her graduate marketing research textbook recommends a product development analysis called *CONJOINT ANALYSIS*. During the introductory interview, the consultant figures out that this technique – provided by the agency – is not appropriate given the client's problem. The brand is imported, is part of a standardized global campaign, and attributes like size, content, advertising, and price have been decided upon by the headquarters. When no attributes can be varied as part of the test, conjoint analysis is rarely the preferred option. Instead a target market segmentation by way of a *CLUSTER ANALYSIS* combined with an analysis of background data and media habits appears to be a better choice. Moreover, the former study costs about three times more than the latter. What should the consultant do? Should he or she go ahead with the conjoint study thereby getting closer to his or her own annual budget target (and give priority to the agency's revenues)? Or should the consultant recommend the better and cheaper solution? Normally, it is assumed that the agency should offer the best and cheapest solution to the client. Therefore, acting otherwise would be unethical.
5. A big management consulting company, T, selects a marketing research agency, Z, for carrying out a major customer satisfaction study for one of T's clients. Some months later, the agency – having 200 employees – offers to send all its employees on a two-day training course at T once every second year – *assumed* that the consulting company would buy all its future marketing research

from agency Z. The deal is scheduled for four years and is then to be renegotiated. T agrees on the deal presuming that it automatically selects Z as supplier next time it needs to collect market research data either for itself or for one of its clients. Is the deal between companies T and Z unethical? The present scenario is rather complicated and disputed. Many researchers working within business-to-business marketing and relationship marketing do not at all regard such a deal as unethical. For these researchers, *reciprocity* is a useful business strategy that fosters “long-term relationships” and is “mutually beneficial.” However, the US Supreme Court has issued critical comments. It called reciprocity in business relations *anticompetitive practice* and ruled that “The practice results in an irrelevant and alien factor intruding into the choice among competing products” . . . “It may increase the difficulty of winning customers for an improved product and . . . tends to discourage product and customer development work.” For much more on the topic of reciprocity in marketing, see Tadjewski (2009).

6. A big retailer wants to establish a customer panel. So, he contacts a research agency and asks it to come up with an appropriate research design. The agency’s consultant works full time for two weeks on all the specifics (screening, recruiting, weighting procedures, statistical algorithms, reporting standards, panel management, costs, etc.). He or she then sends a detailed prospectus to the retailer. For a while, he or she hears nothing. Some months later, he or she learns that the customer panel has been established. Moreover, he or she finds out that the experimental design follows his or her prospectus to the letter. There can be no doubt that the retailer either has established the panel on its own or has forwarded the prospectus to one of the agency’s competitors and asked it to come up with a cheaper price, given the actual research design. This act by the client is clearly unethical and the case should be reported to the country’s association of market research companies. Depending on the specifics, it may be illegal

and the agency could go to the court. Some agencies today ask for a separate fee, say, 10–20% of the project price, for providing a specified bid. In that way, they are at least being compensated for the introductory work. The amount is then deducted from the project price if the company gets the order.

7. Presume that an agency is been contacted by a major bank, Q. The bank’s marketing manager wants to set up an ambitious and comprehensive customer satisfaction index. The index should work as an early warning system for identifying customers who consider changing to a competing bank. The agency makes a research design that the bank accepts and the index system is established. A year later, when the bank manager meets with the manager of a competing bank, S, he or she is told that his or her bank is a client of the same agency and that agency has suggested that they should establish an identical satisfaction index. Since the agency probably has been charging an extra price for developing the index for bank Q, it is unethical to just reuse this for the competing bank, at least without informing Q. Notice that in this case, it is the *agency* that is behaving unethically.

AGENCY – PUBLIC DILEMMA

About two decades ago, R.N. – an elderly marketing professor at a university of a big city in an EU country – wondered about the number of poll-based results published by an upstart opinion poll company. The company, D, was so far unknown and a short time after it was established, it began sending an astonishing number of press releases based on its polls, to the city’s newspapers. The polls primarily dealt with actual political and societal issues. What surprised Prof. R.N. was this: from his many years of working at the university, he had learned that all polling companies he was aware of had a preference for using university students as interviewers. He regularly met his students at shopping malls, at street corners, and so on. Out of interest, he developed a routine of asking the student which polling company she/he was working for. At some point of time,

he began wondering why no one of his students was working for company D. He never met anyone. However, many of the published polls dealt with issues related to the city and the region. Since email was not available at the time, he could not send out a request to all the students. Instead he began asking hundreds of students on the campus but without success. Next, he called the company and asked them to provide him with some specifics about its interviewer base. But since interviewers had to be kept anonymous, they were not able to disclose any specifics.

SIMPLE MINIMUM STANDARDS

What follows is a set of minimum standards based on the marketing literature:

- The length of the interview should not be significantly understated. When contacting a person face-to-face, by phone or by email, one should not state that “it only takes fifteen minutes,” when it actually takes about one hour. As a rule of thumb, an interview should not exceed 30 min. The exception is an in-home interview that can take up to one hour without overburdening the respondent (Malhotra, 2007, p. 325).
- Incentives for completing a questionnaire should be independent of the nature of the answer and should be kept within certain limits. If one projects the top acceptable value of a gift at \$15 as suggested by the White House in 1964 to today, it corresponds to about €115 (Blankenship, 1964). In most cases, though, gifts will be in the range of €5–20. Note that a lottery among respondents is an exception (“A weekend trip for two to Berlin”).
- Ideally, the respondent should be informed about the true purpose of the research as well as about the sponsor. However, in many cases it is necessary to disguise the objective to produce valid results (i.e., when doing mystery shopping, see above). If respondents are told at the beginning of the interview that the purpose of the study is to investigate consumers’ attitudes toward fair-trade products and that the sponsor is the Max Havellar Foundation, then this may bias their responses. A way to handle this ethical dilemma is to inform respondents at the beginning that the purpose of the study and its sponsor are disguised. Additionally, one could tell respondents that the facts are revealed at the end of the interview. If the respondent cannot accept this, he or she can opt out. If he or she accepts, the interview is carried out, and immediately afterward the respondent is informed about the purpose and the sponsor (the procedure is named *debriefing*). If the respondent feels offended or misused his or her information is withdrawn (Malhotra, 2007, p. 244).
- If a respondent has refused to participate or has opted out, he or she should not receive any future unsolicited messages from the agency (mail, phone calls, emails, etc.).
- Basic information like sampling frame, sample size, contact method (phone, email, etc.), exact formulation of questions, computational algorithm, and so on, should be available either to the client or – if published in the press – to the public. Also, if a study is based on a mixture of methods, say, 40% in-home interviews and 60% phone interviews, then this should not be disguised. If a poll is 100% based on an Internet survey, it should not appear only as “a survey.” Change in method across time should be made public. If a survey is conducted as a phone interview one year and as an email interview the following year, this methodological modification should be mentioned.

MARKETING RESEARCH CODE OF ETHICS

Owing to the wealth of ethical dilemmas in marketing research, it has been suggested that a formal certification for marketing research practitioners be established (Ferrell, Hartline, and McDaniel, 1998). To be effective, a certification should be issued by an authoritative institution like an industry association or a government. An example is the *Professional Research Certification* issued by the Marketing Research Association (the certification is given to an individual rather than to a company).

Academic researchers as well as agency managers have suggested setting up a code of decency for marketing researchers.

A code is a broadly written framework within which to determine when the behavior of a researcher is within or out of bounds. Codes can only cover principles of honesty while they cannot cover integrity. Integrity is more difficult to specify. Honesty is merely an avoidance of incorrect behavior, whereas integrity is a voluntary and positive form of honesty, where one takes initiative in acting decently. Basically, a code is a reminder of some principles those in the field are expected to follow (Blankenship, 1964). Unfortunately, violating ethical codes has no consequences for the offender. To make things worse, the greater the reward and the lesser the punishment for indecent behavior, the more likely it is that an individual will practice unethical behavior (Skinner, Dubinsky, and Ferrell, 1988).

Several organizations like the AMA (www.marketingpower.com), the Marketing Research Association (www.mra-net.org), and ESOMAR – the European Society for Opinion and Marketing Research (www.esomar.org) – have developed ethical codes or best-practice principles.

The codes, which can be downloaded from the organizations' web sites, address issues like the following:

- anonymity of the respondent and the right to opt out
- behavior of the interviewer
- description of research method (questionnaire, sample, etc.)
- specification of field work and of statistical analysis
- identification of the sponsor
- ownership of data
- confidentiality of results
- publication of findings
- responsibility for the research
- interviewing children and young people.

Being broad principles, the reader will find them to be of limited value as a practical guide or user's manual for handling new real-life situations. On the other hand, this is better than having no guidelines at all.

Several published studies investigate ethical issues in marketing research. Crawford, (1970) has been interviewing a sample of marketing

executives and research directors. He found, for instance, that about 7 out of 10 questioned regarded the use of hidden tape recorders and one-way mirrors as unethical. However, disguising a study's true purpose was found acceptable by 80%. Akaah (1990) tries to replicate and improve the Crawford study. Although he uses a different method, his major findings appear to support the earlier study. Ferrell, Hartline, and McDaniel (1998) base their sample on AMA member firms. Like earlier studies, the researchers confront respondents with a list of hypothetical situations with ethical dilemmas. Their results indicate differences in perception of ethics between marketing research companies and corporate research departments. It seems that the awareness of ethical principles is somewhat higher in marketing research companies. Lund (2001) used the AMA directory as the sampling frame. He found that in case of a clash of interests marketing research practitioners regard pure ethical standards as being more important than what serves the company best.

While ethics plays an important role in marketing research, ethical principles and standards are also discussed within other marketing disciplines like marketing strategy (see ETHICAL MARKETING AND MARKETING STRATEGY) and international marketing (see GLOBAL MARKETING ETHICS).

ACKNOWLEDGMENT

The author would like to thank Niels J. Blunch for helpful comments on this contribution.

ENDNOTES

¹In this essay we treat the term “*market or marketing research agency*” in a broad manner also including data subcontractors, university professors/students, and independent researchers. “Firm” and “company” are used as synonyms for agency. So, marketing research “entity” or “unit” might have been a better universal term, but to limit confusion we use “agency.”

exploratory research

Vikas Mittal

WHAT IS EXPLORATORY RESEARCH?

As the name suggests, exploratory research in marketing refers to research that helps marketing researchers explore ideas, generate hypotheses, and formulate questions to be subsequently tested and verified in quantitative research. No wonder, exploratory research is typically conducted as a prelude to an informed, conclusive or descriptive research. Some examples of exploratory research include the following:

- A nursing home wanted to find out why its front-line staff had a high turnover rate. To understand what items to measure in the quantitative survey, several focus groups were conducted. They suggested that in addition to pay, respect from coworkers and supervisor, religiosity, self-efficacy, and work-family conflict were key factors affecting job satisfaction and turnover intentions. On the basis of this, items measuring these factors were included in the survey.
- A business school in the Midwest wants to conduct a survey to ascertain the demand for healthcare management programs. To design the various program profiles, a series of focus groups and in-depth interviews were undertaken with physicians, hospital administrators, residents, and nurses (*see SERVICE INNOVATION MANAGEMENT; VOICE OF THE CUSTOMER*).
- A health maintenance organization (HMO) conducted a survey of its members and found that 75% of its members want to be treated with respect by their physician. However, it was not clear what physician behaviors embody the concept of respect. A series of focus groups were undertaken to understand what respect meant to patients. They showed that the primary behaviors defining respect included physicians listening to the patient and not rushing the visit.
- A restaurant owner wanted to open a second branch in a nearby locality. Analysis showed that a weekly patronage rate of 300 guests

would enable the second location to break even. Secondary research using census data showed that not only was the current population base too small to support such a volume, but also that it was likely to shrink in the future. On the basis of this, they decided not to conduct further survey research.

- A major pharmaceutical company wanted to improve the design of its key product – insulin kits. To understand how customers handled and used them, they videotaped different people using their product. On the basis of their observations of how people stored the kits, used them, disposed of them and where they used them, the design team gained new insights. They next held a focus group to further clarify and understand the reasoning behind the usage pattern. Insights from these were incorporated into the product redesign.
- A hospital wanted to understand peoples' reactions to its new website. Two variants of the new website (text heavy and graphics heavy) were launched. Users including patients, physicians, employees, and other constituents were encouraged to post comments online and also discuss them in an online chat room supervised by a focus-group moderator. By monitoring this online content, valuable insights about the website design were obtained.

In general, exploratory research consists of qualitative research and verbal, observational, and projective techniques. As described later, verbal techniques include focus groups and in-depth interviews, observational techniques include ethnographic research, and projective techniques include metaphor elicitation approaches. Sometimes, though not often, firms also analyze existing secondary data to explore possibilities and opportunities for further descriptive and confirmatory research. We focus here on direct-verbal techniques, focus groups and in-depth interviews, as they are the most heavily used forms of exploratory research in marketing.

How does exploratory research differ from quantitative research? In the marketing research industry, the terms *exploratory*

2 exploratory research

research and *qualitative research* are typically used interchangeably. In contrast, marketing researchers use the term *quantitative research* to refer to descriptive research as well as conclusive research. Descriptive research typically consists of a survey, cross-sectional or longitudinal, aimed at describing specific aspects of consumer perceptions, attitudes, and behaviors. Conclusive research usually consists of causal studies designed as an experiment to establish cause-and-effect relationships.

- Quantitative research relies on structured data collection obtained via surveys, secondary data sources (e.g., sales figures, media habits, and so on.) while qualitative research is designed to obtain unstructured data. In the former, for instance, rating scales may be used to ensure that data from all respondents is comparable, and subjected to statistical analysis. In contrast, qualitative research is, by design, unstructured whereby each participant does not respond to the exact same stimulus. This renders data noncomparable for classical statistical analysis.
- In quantitative research, structured data is collected using large sample sizes that are randomly obtained from a population of interest. Using the central limit theorem, then, findings from the random sample can be generalized to the population represented by the sample with a certain margin of error. For instance, in a survey of 200 patients who visited its emergency room in the past six months, a hospital finds 25% to be dissatisfied with the experience. The hospital may conclude with a certain level of confidence (say 90% or 95%) that among all the patients who visited the emergency room, $25 \pm X\%$ may be dissatisfied. In contrast, qualitative research relies on a small judgment sample that is carefully chosen to illuminate all aspects of the phenomenon of interest. Thus, participants in exploratory research should *not* be a random sample of the population of interest. Rather a *purposive* sample using the researcher's judgment should be used. The goal of selecting participants is to obtain maximum diversity in perspectives and opinions. For instance, the hospital may

want to purposely interview patients who visited the emergency room for a variety of reasons ranging from serious trauma, mild fever, accidental poisoning, chest pain, and so on. Detailed in-depth interviewing may reveal differences in experiences enabling the hospital to get a better understanding of *why* people may be dissatisfied, and *how* the reasons for dissatisfaction may vary on the basis of the purpose of the visit.

- Stated differently, exploratory research helps to define the “what and why” while quantitative research helps to quantify “what percent.” For instance, in the earlier example qualitative research allowed the business school to realize that, in addition to curriculum, the format of the offering was a critical decision factor. Further, physicians seem to favor a “weekend only” option over a “weekday-evening” option as the former was perceived to be more practical. The extent of preference, however, could not be ascertained. A quantitative survey of 200 physicians showed that 72% preferred the weekend option, while 28% preferred the weekday – evening option. This information enabled the school's dean to make informed choices.
- The above discussion should also clarify the commonly held misconception that qualitative and quantitative research techniques are rival alternatives to each other. “Should we do a focus group or a survey?” is a question that naive marketing researchers often ask. This is unfortunate. Both research approaches complement each other and should be used to their fullest extent within the context of a comprehensive research program. As explained next, front-end qualitative research provides the building blocks for designing sound quantitative research, and back-end qualitative research provides insights that enrich the quantitative findings. To this end, seasoned marketing researchers, when presenting findings to the top management, will frequently combine both qualitative and quantitative research data during their presentation. Using both types of data not only allows one to draw statistically generalizable conclusions but also fully appreciate the “why” behind

them. In a presentation done for a HMO, researchers first presented the top two reasons for patient dissatisfaction with their visit to a primary-care physician, and these included “waiting time in office is too long” and “interaction with the physician.” Anticipating questions that would arise during the management presentation, the marketing researcher conducted several in-depth interviews with dissatisfied patients to obtain insights into some issues

- Did you have to wait too long outside the office, or inside the examination room? Approximately, how long did you wait? Did anyone provide an explanation for the wait and/or apologize to you? What do you think is a reasonable waiting time?
- What do you mean by “interaction” with the physician? Did the physician listen to you attentively? Do you mean their demeanor and politeness? Were you able to fully understand what they were saying? What other aspects, for you, define physician interaction?

In this way, qualitative research should be viewed as an “insurance policy” that prevents the survey researcher from making important errors of omission and commission. An example of the first is a failure to include important attributes in a survey, while an example of the latter is a failure to use language that the respondent would easily understand, or use categories that are meaningful for the respondent. By incorporating qualitative findings, the researcher can make a much more enriching presentation, and stimulate discussion among the management than if he/she had just presented simple percentages from the survey results. In this example, the discussion about clarifying the meaning of “interaction with the physician” enabled the HMO management to make suggestions to conduct a follow up survey to gather additional information that could be used to address the issues identified in the original survey.

COMPARATIVE OVERVIEW OF EXPLORATORY RESEARCH TECHNIQUES

At the broadest level, exploratory research techniques can be classified into three categories: (i)

verbal-direct, (ii) nonverbal/indirect, and (iii) observational techniques. These are summarized in Table 1.

Verbal-direct techniques are those where the researcher directly asks questions of the participants who in turn verbalize their responses to provide insights. These include focus groups and in-depth interviews. These techniques assume that the participant has the ability and motivation to verbalize their feelings, judgments, thoughts, and intentions. In many cases, such as when discussing concepts that are radical or completely new, or when people do not fully understand their own behavior, these assumptions may be violated. Relative to observational techniques that require elaborate ways to observe and record usage behavior in naturalistic settings, focus groups and in-depth interviews can be conducted with relative ease and are much cheaper and faster. Perhaps this is why they are also the most popular.

Nonverbal and indirect techniques are best suited to surface those issues that respondents are either unable or unwilling to verbalize upon direct questioning (*see* PROJECTIVE TECHNIQUES). In one popular technique involving metaphor elicitations (Zaltman and Coulter, 1995), respondents are asked to collect various pictures from magazines that describe their feelings of a particular phenomenon. Then, a trained interviewer can help them to connect the bridge between deep-unrealized thoughts and verbal articulation of the same. For instance, when asked about the recent stock market turmoil, some investors were unable to articulate how they felt. They were then asked to collect pictures that best represent their feelings. One respondent brought a picture of a boat capsizing in a storm. Under the guidance of a moderator, the respondent then was able to articulate his/her thoughts that he/she felt (i) rudderless, without direction on how to navigate the financial turmoil, (ii) abandoned, and (iii) she wanted more stability.

Ethnography or observational research relies on the direct, unobtrusive observation of people in a naturalistic setting using the product or service of interest (*see* ETHNOGRAPHIC RESEARCH; PERSONAL OBSERVATION; OBSERVATION METHODS). It is typically most useful in designing products such as electronics

4 exploratory research

(e.g., handsets, keyboards, TV, and computer monitors) and other products (e.g., cars) where the usage experience critically depends on sustained interaction between the product and the person (Anderson and Narus, 1998). The resulting experience is captured in the form of pictures, videos, field notes, and drawings and then used to draw conclusions. Observational research is also used in retail settings where consumer patterns in terms of walking the aisles, browsing, and shopping may be captured using a video and then analyzed.

KEY STEPS IN CONDUCTING A FOCUS GROUP OR IDI

Both focus groups and IDIs are the most widely used form of exploratory research (see FOCUS GROUPS AND DEPTH INTERVIEWS). In conducting a focus group (see FOCUS GROUPS AND DEPTH INTERVIEWS), marketing researchers typically follow a series of steps, each step representing a key decision. A brief outline is provided here.

Who should participate? It is useful to have participants who have direct involvement with the issues that are being investigated. These typically include the end users of the product or service under consideration. Other participant groups typically used in marketing research include current customers, prospective customers, lost customers, front-line employees, and company executives. Sometimes, to fully understand competing perspectives, it is also useful to involve those whose involvement is indirect, but who can provide a different take. Thus, in understanding employee satisfaction with their job, a firm also interviewed immediate supervisors to understand the phenomenon from the supervisors' perspective. In other cases, important decision makers (e.g., in the purchase decision) are considered, even though they may not directly use the product. In designing toys targeted toward 9- to 12-year-old kids, the toy company not only held focus groups among children, but also a focus group among parents, the latter being key decision makers. The involvement of multiple stakeholders and their

Table 1 Qualitative research: a comparative view.

| <i>Focus Groups/IDIs (Verbal-Direct)</i> | <i>Projective/metaphor (Nonverbal, Indirect)</i> | <i>Ethnography (Observational)</i> |
|--|--|--|
| Ask people to talk about their behaviors and motivations | Typically people are given a set of pictures and asked to make a collage from them | Observe people's behaviors and motivations |
| Artificial setting and moderator driven | Semi-supervised. Done at facility or at home | Naturalistic setting embedded in context |
| Semistructured and follows a script given to the moderator | Open-ended and varied | Open-ended and varied |
| Respondents articulate their own feelings in their "own words" | Respondents produce a collage from the pictures that best highlight their understanding of the issue/construct | Observers impose their vocabulary and interpretation on respondent's behavior |
| Cheaper to do | Cheaper to do | More expensive to do |
| <i>Data:</i> transcript of discussion | <i>Data:</i> collages by respondents | <i>Data:</i> photos, videos, drawings, field notes, tape-recordings, and so on |
| <i>Focus groups, IDI</i> | <i>Metaphor elicitation</i> | <i>Field observation</i> |

opinions becomes more and more important in business-to-business marketing situations and in multistakeholder industries like healthcare.

What should be discussed? Though unstructured, focus groups and IDIs are not free flowing conversations. Rather, the discussion follows a “moderator’s guide” or an “interview guide.” This is an outline of the topics that need to be covered, and also gives an approximate idea of the time to be spent on each topic. The guide is usually finalized by the moderator, in consultation with the client. Importantly, the moderator or the interviewer may not follow the outline exactly. Rather, an experienced moderator will likely jump back and forth between topics, depending on the flow of the actual focus group. Further, for selected topics the participants may be probed to clarify and provide examples. In other words, the guide provides a roadmap for the discussion.

It should be noted, that the discussion guide for later focus groups or IDIs can differ significantly from earlier ones. Thus, as the research team feels it has gained sufficient insight into a particular topic, the topic may be removed from subsequent focus groups and be replaced by an issue about which further clarification is needed. Sometimes, for example, an issue may surface toward the end of a focus group, and enough time is not available to discuss it. In such cases, the moderator may bring up the issue in a subsequent group to gain insights.

How long should it last? A typical focus group lasts from 60 to 90 minutes, and a typical in-depth interview lasts from 45 to 90 minutes. During this time, the moderator will greet and introduce the participants, orienting them to the “rules” (e.g., not talking over each other and so forth). After that, the discussion proceeds as described in the previous section. While in some instances the interaction can last longer, it is advisable to limit them to no more than 90 minutes. Typically, by that time participants can feel fatigued and may lose the motivation or interest to fully participate in the discussion.

How should the participants be incentivized? Usually, marketing research firms provide both cash and/or noncash incentives, and the magnitude of the incentive can vary depending on

the participants. In one focus group of car dealerships, the research firm donated \$500 to their favorite charity to induce participation. In another focus group among parents of a local Montessori school, a group of MBAs provided food and beverages to thank parents for their participation. In another focus group of nursing aides, an incentive of \$50 was used to recruit participants. An online focus group designed to understand perceptions of different websites promised a chance to win a \$100 gift card for an online shopping site. This illustrates the wide range of incentives that can be offered to secure participation.

How many participants? A typical focus group has between 5 and 10 participants, with an average of seven participants. Research has also shown that about 7–9 focus groups and 20–25 in-depth interviews are enough to surface over 85% of all the customer needs. As explained earlier, researchers should ensure that focus groups and IDIs are conducted in a serial fashion, with later attempts building on and clarifying information obtained in earlier interactions. For a typical focus group, 10–12 participants may be recruited. Accounting for no-shows and cancellations, a desired size of 7–10 participants results.

It is also typical to collect some demographic data on the participants to get an idea of their background. Thus, upon arrival at a focus-group facility, potential participants may be given a short survey to determine eligibility and record basic information. Usually, this is also accompanied by appropriate disclosures to the participants. For instance, if the focus group is being taped or the conversation recorded, the participants should be clearly made aware of it, and preferably their consent should be obtained in writing.

How should the results be described? A key output is the actual transcript of the entire conversation. It is customary to include a video or an audio tape of the focus groups or IDIs in an appendix. Some companies prefer to have a written transcript of the conversation. However, these can run into several hours or hundreds of pages, and are not easily analyzable. Thus, the market researcher will typically use the transcripts to develop key themes that describe the main conclusions of the

focus groups/IDIs along with illustrative quotes. For instance, the theme of “lack of respect” was supported by quotes such as the following, in a focus group of nursing aides working in elder-care facilities: “Doctors were very rude to the aides. They treated everybody horribly,” “it’s like you’re at the bottom of the pole” and “I’d like it if there were more respect for aides”. Doctors and nurses should treat us like partners and rely upon our knowledge of the patients.” There are software packages designed to conduct textual analysis and surface themes, though a discussion of these is beyond the scope of this article (*see* CONTENT ANALYSIS). Nonetheless, organizing the findings of qualitative research around key themes with quotes illustrative of the themes is the most common way of describing and presenting the findings.

In some cases, researchers may be tempted to describe the findings quantitatively. For instance, on the basis of a focus group of six patients, one naïve researcher tried to draw the following conclusion: because “quality of care” was mentioned 23 times during the focus group, it is more important than “doctor makes the correct diagnosis” which was only mentioned three times. The number of times something is mentioned in a focus group is a function of many things, and none of them may be related to its importance. Consider the following possibilities:

- There may be one participant in the focus group who was very verbose and dominated the conversation. This participant may have discussed quality of care at length, perhaps because he/she had a particularly good or bad experience with that aspect of care.
- It may be that all the participants agreed that “doctor makes correct diagnosis” was the most important attribute, but they disagreed about the meaning of “quality of care.” Thus, a lot of time was spent trying to understand what “quality of care” meant to different participants.
- It may be that the physician group commissioning the focus group only wanted to learn about “quality of care” and put that on the moderator’s guide, and that was why it was mentioned many times.

If the researcher is truly interested in understanding the relative importance of these two attributes, then this focus group should be followed up with a quantitative survey. In the survey, respondents could rate all attributes on a 7-point scale, (7 = very important, 1 = not at all important). From that survey, suppose 75% give “doctor makes the correct diagnosis” a rating of 7, and 62% give “quality of care” a rating of 7. Then, using a z -test of proportions a hypothesis test could be conducted, and conclusions about their relative importance to the patients can be drawn.

Should we pay extra for an experienced moderator? Within the constraints of a budget, the answer to the above question is yes, yes, and yes. The importance of a high-quality moderator/interviewer is frequently compared to the importance of a high-quality lawyer at a jury trial. Though it seems easy on the surface, moderating a focus group requires interpersonal, social, organizational, and verbal skills that may take years to develop. For instance, rather than being overly talkative and/or effusive, good moderators fade into the background while directing the focus-group participants and the flow of the conversation. They are firm, particularly with the occasional problem participant, but in a way that does not affect others. Similarly, they are adept at ensuring that the shy or quiet participant’s views are brought forward and incorporated in the discussion. They also take time to fully understand the client’s needs, translating them into a topic-guide and then ensuring that all aspects of the guide are covered in the discussion, as well as in the final report. Not surprisingly, high-quality moderators are in high demand frequently having scheduling backlogs running into weeks if not months.

Should we conduct focus groups or in-depth interviews? Both focus groups and IDIs are direct-verbal techniques designed to elicit the judgments and opinions of the participant (*see* FOCUS GROUPS AND DEPTH INTERVIEWS). When studying sensitive topics such as drug use, cheating, personal hygiene products, and cosmetic surgery, some researchers agonize whether they should use focus groups or

in-depth interviews. On the one hand, some make the argument that an in-depth interview affords respondents privacy because the respondent is alone and can therefore confide in the interviewer. Because of this the respondent can be more forthcoming. In a focus group, they argue, social desirability may distort the respondent's responses. On the other hand, it has been argued that a focus group allows people to feel at ease and put forth their ideas when they see others being forthcoming. Over the years, people have designed many studies to directly compare the outcome of conducting focus groups versus a series of in-depth interviews. Findings show that both techniques yield similar information, with neither technique holding an advantage over the other. What are the reasons for this?

A well-trained focus-group moderator or a well-trained in-depth interviewer can both put respondents at ease and guide them to explore ideas, irrespective of the sensitivity of the topic being discussed. Thus, privacy afforded by an in-depth interview or synergy afforded by a focus group is a poor argument for choosing either. Rather, in practice the choice is driven by the logistics of the project (e.g., timeline and resources) and respondent convenience. For instance, finding that it was cost prohibitive and virtually impossible to invite a company's CEO to a central location, the marketing researcher decided to conduct in-depth interviews via telephone to understand sustainability initiatives at these companies. In many cases, a mix of focus groups and in-depth interviews is used. For instance, a series of in-depth interviews can be done following a focus group to gain further insights into the issues that surface in a focus group. By staggering the interviews, ideas obtained in previous encounters can be elaborated upon in subsequent ones. In another study, researchers wanted to understand factors that can improve or impede retention in high-stress jobs such as taking care of the elderly in nursing homes. They wanted to reach out to CNAs (certified nurse aides) both in urban and rural areas. Because of the proximity of several nursing homes in urban areas, it was easy to conduct focus groups. However, owing to the inability of CNAs in rural areas to travel long distances, telephonic interviews were conducted. Later, a

comparison showed remarkably similar results for participants in urban and rural locations, and thus, data from both methodologies were combined for the sake of analysis and insights.

COMPLEMENTARY USE OF EXPLORATORY AND QUANTITATIVE RESEARCH

Sometimes qualitative research is done as stand-alone research to gain an in-depth understanding of a phenomenon, such as customer reactions to a product concept or advertising copy. Frequently, however, it is used in conjunction with quantitative research, most notably survey research. In this manner, the use of qualitative research can be subdivided into three parts, each corresponding to different stages of the survey research

- *Front-end exploratory research:* One main use of exploratory research is to generate survey content such as key categories of constructs to be included, survey items to measure the constructs, and specific language corresponding to each construct. For instance, a bank wanted to design a customer satisfaction survey to measure satisfaction with customers' visits to the bank branches. Observation of several branches and focus groups with customers identified several components, including waiting time, interaction with tellers, products and services, and fees. Then, specific items corresponding to each area were developed by studying the focus-group transcripts. Qualitative research can be very useful to understand the vocabulary customers use to describe their experiences and/or the firm's brand. For instance, a company interested in pricing research wanted to design a survey to measure the likelihood of purchase at different shampoo prices per ounce. They did not know how to frame the pricing question for the survey. Qualitative research showed that the customers thought in terms of the price of a bottle of shampoo (small, medium, and large) and not per ounce. On the basis of this insight, the survey was designed to incorporate the customers' mindset, and enabled the firm to gain valuable insights.

- *In-process qualitative research:* Frequently referred to as “pretesting” and “cognitive testing” of a survey, in-process qualitative research is used to refine an initial draft of a survey (see PRETESTING A QUESTIONNAIRE; QUESTIONNAIRE DESIGN). The survey is administered to a respondent with a researcher monitoring the respondents’ verbal and nonverbal behavior. For example, if the respondent takes too long to answer a question, it may be that the question is ambiguous and/or the response categories do not make sense. Sometimes the respondent may leave a question unanswered. The researcher can then ascertain the reason for nonresponse which can range from unclear question wording, to multimeaning response options, to offensively framed questions. The researcher can then probe and clarify such issues, to revise and refine the survey accordingly.
- *Back-end qualitative research:* Once a survey is completed, sometimes a focus-group or in-depth interviews can help clarify observed patterns of results, or the logic behind them. For instance, a physician found that 35% of his/her patients viewed his/her as “nonresponsive to my needs.” A series of in-depth interviews showed that patients felt he/she (i) did not acknowledge their greeting in his/her office; (ii) was seen as unwilling to give referrals, and (iii) frequently made patients wait over 30 minutes in the office. The physician decided to address these issues to improve his/her perceptions of being responsive to patient needs.

MISUSING QUALITATIVE RESEARCH

There is also a potential danger that qualitative research may be misused and abused. There are many occasions and instances where qualitative research should not be used. In particular, misuse of qualitative research can occur if qualitative research is used as a substitute for quantitative research. Often, people will cite qualitative research to make assertions such as “attribute ‘X’ was mentioned by many respondents in the focus group. Therefore, it must be very important for our customers.” As explained before,

the only conclusion one should be drawing is that “attribute ‘X’ that was mentioned in the focus group should be part of the quantitative survey.” An attribute may generate a lot of discussion for many reasons and not necessarily because it is important. In some cases, managers’ misuse qualitative research by selectively using quotes from respondents to push their own agenda/viewpoints. This should be avoided at all costs by sharing the actual transcript (typed or as a video file) with everyone and fostering a detailed discussion of the findings.

Finally, one should resist the temptation of “quickly throwing together” a focus group to get “some idea” about consumer needs. On the contrary, just like quantitative research, qualitative research should be carefully planned in terms of the content of discussion (e.g., moderator’s guide), participant selection, venue, transcription of data, interpretation of data, and the nature and strength of conclusions drawn. By following proper guidelines one can not only maximize the impact of qualitative research, but also ensure it is not abused by others.

EMERGING TRENDS

The spread of the Internet has also transformed qualitative research. As boundaries of time, distance, and content are blurred exciting new avenues for capturing data for exploratory research have opened (see WEB SURVEYS). For example,

- Online focus groups allow participants to exchange ideas under the guidance of a trained moderator. Participants log into a secure chat room where the online moderator can conduct the focus group. As video conferencing technology proliferates, distance-based focus groups will be further transformed.
- Companies are paying attention to online blogs (from its customers and others), online comments (e.g., epinions.com), and other sources which provide useful exploratory research. Insights from these sources can guide the design and focus of quantitative research to a large extent.
- Online videos and posts from interested customers can be rich sources of observational research. Ethnography will become

more prevalent as customers become more open to allowing companies to remotely observe product and brand usage in real time.

- Intranets within a company have become popular for eliciting employee comments to gain qualitative insights and feedback. For instance, initial product testing can be conducted with the employees. Sometimes, they may be asked to provide feedback on branding initiatives such as the redesign of the company's website.
- Finally, researchers have also begun to quantitatively analyze large sources of qualitative data. For instance, Yahoo users post thousands of movie reviews online. These can be quantitatively analyzed to understand various aspects of movies that can predict viewer tastes.

CONCLUDING COMMENTS

Exploratory research is the foundation upon which the success of a marketing research effort is built. It should be an integral part

of any marketing research effort, and not an afterthought. We hope that this article will provide the reader with a basic foundation for conducting exploratory research to gain marketing insights that may drive organizational success.

marketing research process

Gaurav Bhalla

INTRODUCTION

Capital One is one of the largest issuers of credit cards in the United States. However, Capital One is more than just a credit card company. Capital One is also a retail branch banking company. A few years ago it acquired Hibernia, North Fork Bank, and Superior Savings of New England, N.A., which gave it a footprint of over 700 branches and 1100 ATMs in New York, New Jersey, Connecticut, Virginia, Texas, and Louisiana.

Let us consider 2004, before the acquisitions took place and imagine that the Executive Team is discussing the diversification from credit cards to retail banking. The CEO wants to know if Capital One's brand equity from credit cards will extend to banking. Most of the executives in the room are positive that it will. However, the CEO requests that a formal marketing research (MR) study be commissioned to get the customer's perspective.

As you can imagine, to comply with this request, the MR professionals at Capital One will have to make a series of systematic and related decisions, such as the following:

- Agreeing on the specific marketing question to be addressed.
- Translating the marketing question into specific research objectives.
- Deciding on what type of data to collect and how to collect it.
- Identifying the subpopulations to be included in the sample: all potential retail banking customers or just credit card holders, and so on.

As the mini case study illustrates, one of the defining characteristics of contemporary organizations is the use of formal information to make sound decisions. Gut feel and intuition are necessary, but not sufficient. The CEO could have gone with a majority vote, but decided instead to supplement his/her team's judgment with the market data. MR is one of the most frequently used methods to formally collect market data.

For an MR project to yield the information desired, it is important that the professionals in charge of executing the project follow a systematic method, as discussed in the mini case study.

The traditional MR literature refers to the sequential systematic steps taken by MR professionals for the execution of MR projects as the marketing research process (MRP). The rest of this article will discuss this traditional MRP and its various constituent steps in detail. Following that, the article will discuss certain modifications and adaptations to the traditional model, on the basis of how the MRP may actually play out in practice. Lastly, the article will also discuss on how the emphasis and focus at a number of companies is shifting away from the transactional aspects of the MR process to thinking of it as a business process, where the goal of MR is not merely to provide results, findings, and insights, but to influence business outcomes.

OVERVIEW

Most common and popular MR reference sources describe the MR process similarly (Kumar, Aaker, and Day, 2009; Malhotra, 2007; Zikmund and Babin, 2007). Broadly speaking the MR process comprises of three main phases (*see also* MARKETING RESEARCH PROPOSAL):

- Predesign or planning phase (*see also* CRITERIA FOR EVALUATING SECONDARY DATA)
- Design phase (*see also* EXPLORATORY RESEARCH; EXPERIMENTAL DESIGN; FOCUS GROUPS AND DEPTH INTERVIEWS; OBSERVATION METHODS; SURVEY RESEARCH)
- Execution or implementation phase (*see also* WEB SURVEYS; FOCUS GROUPS AND DEPTH INTERVIEWS).

The focus of the predesign or planning phase is to ensure that all stake holders are in agreement on why the research is being conducted, which business questions will be addressed by the research, the specific research objectives that will guide the data collection, and whether or not the data proposed to be collected will incrementally influence business decision-making. The intent is to establish clarity of purpose, develop

2 marketing research process

focus for data collection, and ensure that the information collected will deliver incremental value to the decision maker.

The design phase is concerned with issues related to the best, or most suited, approach for data collection, and with tactical details concerning data collection, such as questionnaire design, types of questions that should be asked, and the types of analysis that would help extract the maximum information from the data. Decisions concerning the best, or most suitable, approach for data collection are always taken in the context of the purpose and focus established in the predesign phase. Tactical decisions are constrained by the overall research approach preferred; they also influence decisions concerning the overall approach. Take the example of a concept test. If data are being collected over the telephone, it would be difficult to administer questions that require real time evaluation of visual stimuli. If the client believes that without evaluating pictures of concepts obtaining accurate respondent perceptions will be difficult, then the telephone data collection approach will have to be modified.

The execution or implementation phase deals entirely with the collection, analysis, reporting of data, findings, conclusions, and insights. This phase also involves making recommendations to the decision maker, on the basis of the insights acquired, concerning alternatives for action and their relative merits.

Properly conceived and executed, all three phases collectively determine the overall quality and value of the research conducted. It is not useful to discuss which phase is more important, owing to the interdependence that exists between the three phases. To illustrate, if the business and/or research problem is inaccurately or incompletely stated, no matter how brilliant the research design, the outcome of the research will not be helpful to the decision maker. Similarly, errors in designing the research can reduce the overall quality of the research, no matter how brilliant the execution. And finally, the best planned and designed research can be defeated by flaws in execution – poor sample quality, ill-trained interviewers, and weak analysis can all detract from the overall quality of the research.

Figure 1 depicts the three macrophases of the research process and the key decisions within each phase.

PREDESIGN OR PLANNING PHASE

Management thinking is not unlike fashion. Certain ideas catch on and then dominate the consciousness and agendas of companies, before giving way to the next. Several candidates come to mind when one looks in the rear view mirror – total quality management (TQM), customer satisfaction, six sigma, customer loyalty, customer relationship marketing (CRM), and so on. They have all had their time in the sun and then faded into the background.

Customer focus is today's differentiator. Every company today claims to be customer focused; yet when you experience the company, its products, its people, and its service, the impression that you get is quite contrary. Imagine you are the chief marketing officer (CMO) of an organization that operates at the intersection of customer service and retail – like Home Depot (world's largest home improvement retailer) or Best Buy (world's largest specialty consumer electronics retailer). You are well aware that your company claims to be very customer focused, to provide unimpeachable service, and to always put the customers' interests over the company's interests. Yet, you have heard from friends and family and from newspaper reports that most consumers think that companies are not customer friendly and that their customer service stinks. You are also aware that if you google for the term 'customer service stinks' you will get thousands of links, blogs, posts, news articles, books, and so on, complaining about companies and the service they provide.

Clearly, there is a disconnect between how the company views its service offering and what the market believes it is getting. Can MR help the CMO? Where should the CMO begin – internally with front-line employees, or externally with disgruntled customers? But is being disgruntled what it is all about? The CMO has also heard that not everyone who receives poor service complains. But, since the company is committed to providing excellent service, technically speaking, every customer who did

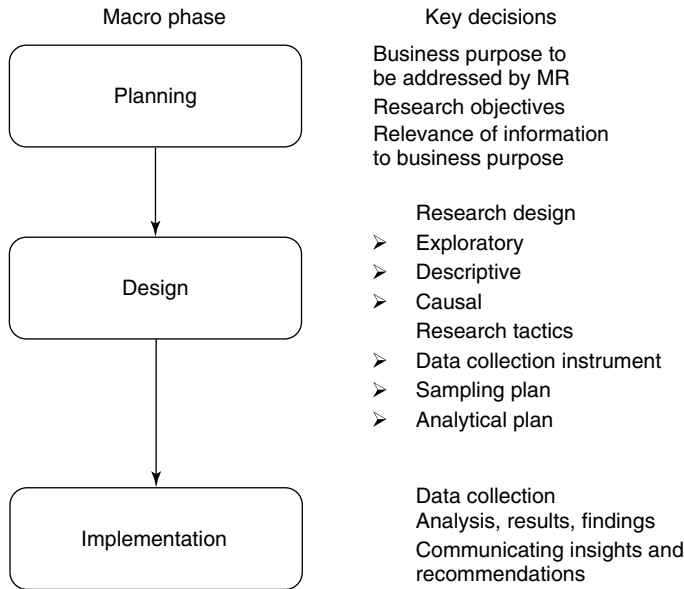

Figure 1 The marketing research process.

not perceive receiving excellent service reflects underachievement on the part of the service department. How should the CMO proceed to identify the nature and sources of this underachievement and then, to root it out?

Hopefully, the mini case study above should demonstrate that decision making in the business world is not always straightforward or easy. Business situations are messy and multidimensional, making it difficult to decide the subset of issues to focus on and their prioritization. It is very easy to imagine two MR professionals interacting with the CEO in the above scenario, one recommending that the company spend time gathering more facts before conducting formal MR and the other recommending proceeding with formal MR as all the facts that are needed are already available.

To be certain that significant aspects of the problem are being addressed and that following the research decisions can be made without the need to collect additional data, the following steps should prove helpful.

- No matter how complex the problem/opportunity, it always helps to generate a set of hypotheses or speculations

as to the reasons contributing to the problem/opportunity. If there is uncertainty concerning potential contributors, making it difficult to hypothesize, then appropriate investments should be made in fact finding and desk research to learn more about the relevant dimensions of the target problem/opportunity.

- Assuming enough is known about the service problem discussed in the case study, a few potential hypotheses could be the following:
 - Poorly trained service representatives.
 - Ambiguous processes on how to handle customer complaints.
 - Inadequate communication with the customers on service options and complaining procedures.
 - Unduly long wait, hold, and lead times in handling customer complaints/returns.
- No company has enough time or resources to research all issues that it is uncertain about. Dealing with uncertainty and risk of incomplete information is par for the course in today's organizations. Once the set of hypotheses has been generated, managerial judgment and commercial astuteness will need to be exercised in making trade-offs

4 marketing research process

and determining a subset of hypotheses to be researched.

- A forward-backward approach can help in making these trade-offs. For example, the CMO can telescope forward to the point of decision making and articulate the information inputs that will enable him/her to make an effective decision.
- The MR professional can now work backward from these information inputs to the hypothesized reasons to identify the subset of hypotheses that should determine the focus of the research. As indicated above, if the subset of hypotheses to be researched is unduly large, trade-offs will have to be made.

The iterative thinking recommended above has one purpose – to make certain that the business problem being addressed is relevant, given the situation the company finds itself in. The ability to get to the heart of a problem is an invaluable skill. This skill can be nurtured and developed by investing in heuristics that emphasize iterative thinking, as recommended above, till it becomes second nature.

In the predesign phase, most standard textbooks of MR discuss the need to estimate the value of information, as all MR has a cost attached to it. The idea is that if the decision can proceed with certainty, independent of the research information collected, then the proposed information has zero value. This author has no desire to discount concepts like the expected value of information. However, in the day-to-day press of the commercial world, the determination of the incremental value of information is essentially subjective. To a very large extent, the decision maker and his/her key cohorts determine whether the information is likely to be valuable or not.

DESIGN PHASE

The key objective during this phase is to develop a blueprint for data collection, with the overall goal being the fulfillment of the study's business and research objectives. The decisions made during this phase are both conscious and iterative. Decisions made earlier in the research process, such as objectives and

scope, influence subsequent decisions in the MRP such as approach and analysis. However, decisions concerning data collection and analysis can also influence decisions made previously. For example, lack of broadband Internet access among certain sections of the population may lead to a revision in research design; purity of design, emphasizing a single method of data collection may be sacrificed to accommodate a larger cross section of the population.

Here, just as in the case of the overall MRP, the MR literature is unanimous in its classification and discussion of major research approaches. Most texts classify research into three categories – exploratory, descriptive, and causal. Descriptive and causal can be further subclassified; for example, descriptive research can be either cross-sectional (one sample at one point in time), or longitudinal (repeated samples at successive points in time). Figure 2 summarizes the main and subcategories of research design.

For the sake of completeness, it is important to point out that some MR text and reference sources use a different classification system. Brief details are provided below.

- Research approaches are broadly classified in two categories – qualitative and quantitative.
- Qualitative research approaches are then subclassified into categories, such as in-depth interviews, small group research (focus groups), observational research, and so on.
- Similarly, quantitative research approaches are subclassified into categories such as descriptive, evaluative, predictive, and so on. The subcategories may themselves be stratified further. For example, there are instances where predictive research is classified further into experimental design and modeling research.

Additionally, there are specialist designs that are not discussed in this article or in most MR text books (*see also* ETHNOGRAPHIC RESEARCH; MOTIVATION RESEARCH; OBSERVATION METHODS; PERSONAL OBSERVATION; PROJECTIVE TECHNIQUES). For example, qualitative researchers may prefer the narrative research approach, which analyzes respondents' first person stories recorded as narrative text

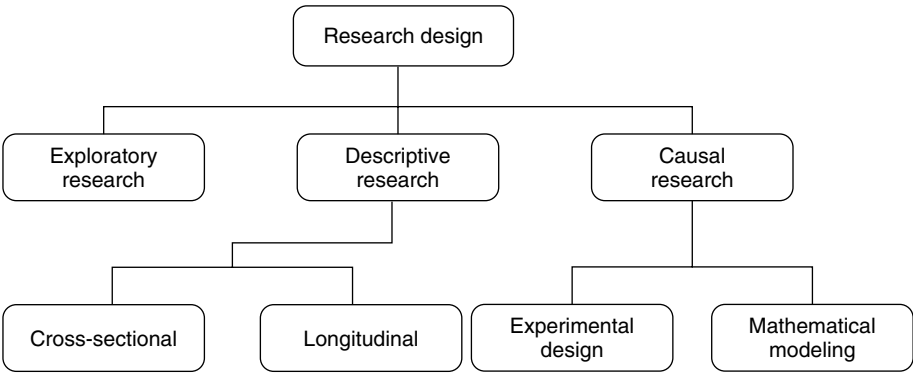

Figure 2 Taxonomy of research designs.

(Clandinin and Connelly, 1989). Similarly, given the increasing popularity of social media, quantitative researchers may prefer to use specialized agent-based modeling techniques to study the spread of influence and the diffusion of innovations (Bonabeau, 2002). Generally speaking, specialized qualitative research approaches are usually borrowed from psychology, sociology, and anthropology, while specialized quantitative approaches are usually borrowed from disciplines like econometrics, statistics, and computer science.

Lastly, even though this section and MR text books discuss the various approaches to data collection as separate activities, power in research design is often derived by combining research approaches. For example, researchers interested in modeling the breakfast food choices of different ethnic groups (Hispanic, Asian Indian, African American, White Caucasians, and so on.) may use qualitative research to first understand the context variables driving choice (family size, budget, time, perceived importance of breakfast, food preferences – cold, hot, freshly cooked, precooked, and so on). This could then be followed up by a data-collection-modeling phase, which would gather descriptive data from a larger number of respondents and then model it using statistical methods like Logit modeling (*see also* LOGIT MODEL).

EXECUTION AND IMPLEMENTATION PHASE

The execution and implementation phase is concerned with data collection, analysis, and

communication of results, insights, and recommendations.

Traditionally, in-person, mail, and telephone methods have dominated MR data collection. With the growing popularity of computers in the 1980s, computer aided interviewing grew in importance for both the in-person and telephone formats. Since the mid-1990s, with the increase in ownership of PCs and in Internet usage, the share of web-based methods of data collection has increased significantly. Figure 3 presents a classification of key data collection options available to a researcher.

Activities related to data collection, including questionnaire writing and analysis have been significantly transformed by the availability of specialized software. The goal of data collection software, like Confirmit, MarketTools, and Surveywriter is to help make the data collection phase efficient and painless, by passing and assigning the drudgery and routine elements to the software.

The goal of the analysis software (SAS, SPSS, and so on), on the other hand, is to disseminate statistical computing power as widely as possible; computing power was once available only to those with specialized training. As a result, lack of knowledge of how the statistical procedures work is no longer a barrier to designing specific types of research. For example, an analyst does not need to know the mathematical and/or statistical intricacies of utility estimation to design a conjoint study. Admittedly, more complex studies requiring complicated experimental designs will still require relevant

Computer assisted data collection is not considered as a separate data collection methodology, but as an alternative to paper-based approaches for in-person, telephone, and mail data collection methodologies.

(1) Mall, airport, retail store

(2) Random digit dialing

Figure 3 Classification of data collection methods.

knowledge, limiting the number of research companies able to offer the service.

Fortunately, knowledge still plays a role in designing research, in analyzing data, and in drawing meaningful insights from the analysis. However, at the cost of oversimplifying, it can be safely said that the widespread availability of relevant literature, MR courses/training, software, and other technological aids have made the competitive space for MR services much flatter than it once was.

Statistical procedures, both univariate and multivariate, still form the backbone of most of the analysis conducted on MR data (*see also* CLUSTER ANALYSIS; CONJOINT ANALYSIS; EXPLORATORY FACTOR ANALYSIS; MULTIDIMENSIONAL SCALING OF PREFERENCE DATA; DISCRIMINANT ANALYSIS FOR MARKETING RESEARCH APPLICATIONS; ANALYSIS OF VARIANCE AND COVARIANCE; MULTIPLE REGRESSION). Over the years, as the demand for predictive research has increased, this repertoire has been supplemented with econometric and statistical procedures that emphasize nonlinear estimation and analysis procedures. Additionally, the new procedures also allow for simulation of results to allow the sponsor of the research to test and evaluate a variety of decision scenarios, without the need to collect new data.

Following the completion of an MR project, it is customary for the agency or the department that has conducted the research to share:

- results and insights with the sponsors and key stakeholders who commissioned the research and;

- make recommendations about possible courses of action, on the basis of the results of the study.

PowerPoint presentations are the mainstay here. Few MR presentations use a truly multimedia platform to communicate results; in a few instances, where qualitative or ethnographic research is conducted, videos of respondents in their natural environments sharing details relevant to the study may be shared with the sponsors of the study. In some instances, following the presentation of results, work groups may also be set up to determine what actions should be taken on the basis of the insights acquired, and what future research needs to be done, if any, to support future decision making.

MARKETING RESEARCH PROCESS IN PRACTICE

The traditional approach, as presented and discussed in this article and other MR texts, reflects a linear, sequential, rational approach to decision making. Like all models, it captures only a portion of reality. The purpose of this section is to help the reader understand that in the commercial world the execution of MR projects and the acquisition of information relevant to decision making does not always proceed in a systematic step-by-step manner. A few factors that contribute to compression, adaptation, and modification of the MRP discussed previously are listed below:

- Information is not just acquired through formal MR studies, but it is also acquired

through secondary and syndicated data sources.

- Time compression – fire fighting is a common feature of daily life at companies.
- Demonstration effect – management ideas are not exempt from fashion cycles.
- *Inertia* – in the case of MR, defined as continuous motion – keeping a study going, as opposed to launching it *ab initio*.

A brief discussion of how each of the above factors modifies the traditional-rational MRP follows.

Secondary/Syndicated data. Several companies, like Nielsen, IRI, Corporate Executive Board, Forrester, and Gartner are in the business of producing and selling information. Their clients typically include companies like P&G, Hershey, HP, Citi, and Pfizer – companies with large flourishing MR departments who routinely use MR information and insights to inform their decision making. In short, companies use a mix of primary research (research that they initiate and conduct themselves, or through their agencies) and secondary/syndicated research (research designed and conducted by other companies) to build their market information stores.

In the case of secondary/syndicated data, the MRP described in Figure 1 may not be followed literally. Stages may be either compressed or skipped. Take the instance of Nielsen or IMS, two of the largest aggregators of market data, the former aggregating retail sales data and the latter physician prescription data. Once a company decides that it will be aggregating certain types of data, the sequence of decisions may shift very rapidly to critical variables like sample design, data recording, and data base creation.

From a company's point of view as well, the goal is different. Take the instance of P&G and Nielsen. On 22 July 2008, the Nielsen Company announced that it had extended its agreement with The Procter & Gamble Company to provide US consumer marketing information and insights. Under the multiyear agreement, Nielsen will provide P&G with marketing information and technology services, including retail tracking, insights on consumer purchase behavior, marketing analytics, and

Nielsen Answers™, Nielsen's technology-based business intelligence solution. Nielsen will help P&G understand and develop new ways to market to its consumers.

What was P&G's motivation to extend the contract with Nielsen? Not some narrowly defined business or marketing problem, but a broadly defined business need. In the words of Garry Terrell, section manager, U.S. Market Measurements, P&G – *“the collaboration with Nielsen will enable us to access the data and research we need to drive business-building insights and innovation that both excites and delights our U.S. customers.”*

Time compression. In certain cases, for reasons associated with fire-fighting drills and/or crisis management, there is not enough time for full-blown formality and a detailed consideration of all decision variables in a systematic, sequential manner. Take the instance of pharmaceutical marketing. The Food and Drug Administration (FDA) and pharmaceutical manufacturers often use “*Dear Doctor*” letters to alert physicians about drug safety. For example, in March 2004, the FDA asked all manufacturers of a typical antipsychotic medication to add a warning statement describing the increased risk of hyperglycemia and diabetes in patients taking these medications. Drugs in the antipsychotic class covered by the FDA request included Zyprexa® (olanzapine, Lilly), Clozaril® (clozapine, Novartis), Risperdal® (risperidone, Janssen), Seroquel® (quetiapine, AstraZeneca), Geodon® (ziprasidone, Pfizer), and Abilify® (aripiprazole, Bristol-Myers Squibb and Otsuka American Pharmaceutical).

Dear Doctor letters do have a negative impact on physician prescribing. To what extent and for how long, is the key unknown. It is not unreasonable to expect marketing managers at all of the companies mentioned above to scramble to launch studies to get more data on those unknowns for their respective businesses. Since speed is of the essence, the following deviations may take place from the MRP outlined in Figure 1:

- A single research objective, driven by external circumstances.

8 marketing research process

- Opting for a research design that can deliver results faster, even though it may not be optimum.
- The need for speedy data collection may completely determine the types of questions and the type of data collected.
- Analysis may be sacrificed – reporting of counts and frequencies may suffice.

Demonstration effect. We live in a networked world. News of companies trying new and interesting things are reported frequently. In addition, company representatives are constantly showcasing their achievements and competencies at conferences. It is not unusual for an executive from a certain company hear about what a competitor or another admired company has done and want that replicated in his/her own company.

The use of ethnography in MR provides an excellent example to understand how the demonstration effect can shrink the formal MR process. In recent years, there has been a sharp increase in the use of ethnographic approaches in qualitative MR to gain a deeper and more context-bound understanding of customers, their attitudes, and their behaviors. Popular media, like BusinessWeek, Wall Street Journal, and Fortune have been quick to catch on and have featured full-length features on how the most innovative companies in the world are hiring anthropologists and using ethnography to boost their innovation and product design efforts.

To illustrate, the 14 March 2007 issue of BusinessWeek carried an interview with Jan Chipchase, an interface designer and a user anthropologist at the Nokia Research Center. The article reported how ethnographic research approaches were used to understand about how people share objects, such as cell phones. In Africa, and several other places, increasingly a cell phone is shared. A family might have one. A village might have one, or someone who runs a phone kiosk in a village might have one. The purpose motivating the research was idea generation concerning how Nokia could redesign the mobile phone and the communication experience to be more suitable for sharing.

An executive at HP, Intel, or some other PC company may read this article and ask, if Nokia can do this why can't we? After all Internet cafes where computers are shared already exist in several parts of Asia and Europe. The appeal of a new idea tried by a competitor, or an admired company, may be strong enough to circumvent much of the formal MRP. The brief may be direct and simple – to conduct ethnographic research in less affluent countries to understand PC sharing behavior and the demands that it places on machine and user interface design.

Inertia. The fundamental assumption underlying the traditional MRP is that a study is to be launched. But in several cases, referred to as *longitudinal research*, *continuous research*, or *tracking research*, the study has already been launched in some previous time period. The goal of the researcher therefore is not to launch a study, but to sustain its inertia – keep it going.

Examples of continuous or tracking research from several different sectors are presented below:

- Technology companies like IBM and HP may conduct tracking research to understand purchase and consumption trends for hardware, services, printers, and consumables, like printer ink.
- Service companies like restaurants, banks, and retail stores conduct customer satisfaction tracking studies to monitor customers' experience with the store, its offerings, and its front-line customer facing employees.
- Automobile and consumer electronics companies conduct new buyer tracking research to monitor buyer experience and postpurchase dissonance or regret.
- Social research companies conduct tracking research to monitor shifts in attitudes toward public policy (education, healthcare, trade, subsidies, taxation); political polling companies conduct tracking research to monitor shifts in preferences for different candidates contesting an election.

Since the research is already in motion and the principal goal is to provide an unbroken basis for making comparisons and drawing conclusions, the fundamental focus of the MRP is

housekeeping. Barring occasional adjustments to sample design, question wording, and measurement scales, the principal focus is on flawless and timely implementation. Very rarely does the researcher cycle through the entire MRP.

MARKETING RESEARCH AND ITS DISCONTENTS: IMPLICATIONS FOR THE MRP

Every discipline has its own grammar and MR is no exception. Traditional MR is predicated on a simple rule – a business issue can be translated into a set of questions, qualitative or quantitative, which can then be asked to respondents, who in turn want to and are able to answer them, which responses when properly analyzed result in meaningful insights.

In most of its early years, this formula worked very well. Companies that embraced and adopted emerging principles and techniques of MR and used its output intelligently were actually able to generate a competitive advantage. Reports of business success using specific MR techniques spread quickly with the help of academic literature and the business press, creating fashion cycles and mass adoption. Attitude research using Likert scales, advertising effectiveness research based on low involvement theories, trade-off analysis using conjoint research, and customer satisfaction research to name a few have been used enthusiastically and extensively. And while there was the occasional highly publicized howler, perhaps none more famous than the introduction and subsequent withdrawal of New Coke, success stories – like the design of the Marriott Courtyard, the introduction of Ford Taurus, and the use of segmentation research by banks and credit card issuers – continued raking up points for MR.

In recent years, the relationship between MR and its key stakeholders has soured, the extent of which varies depending on who is providing the reasons. As with most things that are successful, the expectations from MR have increased tremendously. And the general opinion is that MR has not responded effectively. The reader might wonder why we are discussing the practice of MR, when the focus of the article is on the MRP. The reason is simple. How MR is designed and executed (MRP) is a direct function of how MR is conceptualized and used.

It would be difficult, and its not necessary, to document every grievance against MR. As such, only a few important criticisms are recognized below.

- MR is very transaction oriented, one project at a time, and has never really evolved into a true information or a decision support system.
- The function and the process are very technique driven – greater focus on research designs and analytics than on business issues.
- Businesses today face greater uncertainty and risk, emphasizing anticipation and prediction – traditional MR tools are more suited for description.
- Asking consumers questions is only one source of information and insights.
- Managers coordinate business systems to drive business performance – like profitable long-term growth; MR should focus on the entire system and not just elements of it.

While preparing to write this article, the author had informal in-person and telephone discussions with several executives (approximately seven) in charge of MR departments at large product/service companies in the Financial, technology, consumer packaged goods, and healthcare sectors. The purpose of the conversation in each case was to understand how the MRP actually unfolds in their companies. It is important to point out that these companies have made significant changes in the way they have organized their businesses and the MR function, including what they call it. The term *MR Department* has all but vanished; today most companies prefer labels like Customer Insights, Consumer Insights, Market Intelligence, and so on.

Key points that emerged in the discussions are presented below.

- Unlike the traditional MRP, the starting point is not a business decision, but a business agenda. The focus is not so much on a single decision maker, but on a collection of decision makers of a larger unit – such as a category (beverages), segment (on-the-move consumption), or market (retail banking).
- There is a greater emphasis today to plug information gaps, not merely fulfill research

obligations by checking off research objectives.

- There is greater pressure on MR to adopt a comprehensive, multidimensional, approach to information; data integration is at a premium.
- Distinct preference for influencing business outcomes, not just generating results and insights.
- Greater expectations of the function to be effective along a continuum ranging from business maintenance to business transformation.

This is not to say that the traditional MRP is dead and will never be employed. On the contrary, for projects that can be structured and where there is a dominant single need – to test a concept, to discover subsegments in a growing market, to estimate price and promotion elasticity – traditional MRP still is king! However, the number of situations that fit the above description is decreasing, owing to the fundamental changes in how businesses create and deliver value to their customers. Consequently, traditional MRP will continue to contribute, albeit to a smaller fraction of the total information needs of a company or a business unit.

As mentioned in the previous paragraph, significant changes are taking place in the environments companies operate in today and in the way they conduct their business. The most important among them are as follows:

- Greater environmental uncertainty and complexity.
- Future and organic business growth both likely to be extremely challenging for virtually all companies.
- Increase in social media usage, user generated content, and information generation in peer-to-peer forums and aggregator forums, most of which is free.
- Increased collaboration and interdependence between companies and all stakeholders in a company's ecosystem – other companies, governments, nongovernment institutions, customers, consumers, and suppliers.

These changes affect how companies gather and use information. They also influence the

perceptions of the companies in terms of what information outcomes they consider to be useful and relevant. This article would be doing a disservice to the reader if it did not draw his/her attention to these developments and the implications it has for the practice of MR and the implementation of information acquisition and dissemination programs.

On the basis of discussions with a small set of practitioners and the developments discussed above, a forward-looking perspective is provided in Figure 4. It is labeled – A proposed information process for influencing business outcomes – to accurately depict its focus; research data obtained by asking questions to respondents is only a part of this more comprehensive focus. The proposed model is conceptualized to have four macrophases as follows:

- *Issue identification.* The purpose of this phase is to generate an inventory of issues relevant for the achievement of current business goals and for helping bring to market future business aspirations
- *Information need assessment.* The focus of this phase is to actually start at the end, articulate key information that will be needed for the system to implement initiatives to achieve its business goals, and then work back to identify information gaps
- *Integration of insights and perspectives.* From a large number of sources (open source, secondary, syndicated, primary); using several types of data (self reported, web conversations, opinions and ratings, attitudes, behavior); using a variety of data collection methods (obtrusive, nonobtrusive, observational, surveys); and a variety of analytical tools (analysis, mining, extrapolation prediction, modeling)
- *Inspire execution.* The next generation information system must inspire and guide execution and discuss implementation alternatives with accompanying risks and benefits.

CONCLUSION

Companies like, P&G, Capital One, Hershey, and HP regularly spend large amounts of resources, human and financial, on MR projects to improve the quality and effectiveness of their

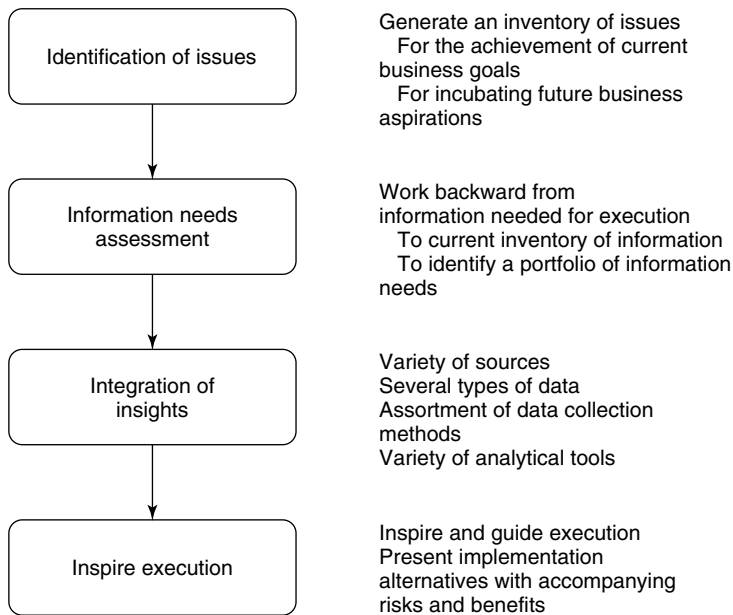

Figure 4 A proposed information process for influencing business outcomes.

business and marketing decision-making. As a large number of professionals and agencies are involved in conducting MR studies, both clients sponsoring MR projects and companies offering MR services stand to benefit if standardized processes can be followed by all involved. The MRP is a key component to standardizing the approach to data collection and ensuring a consistent, acceptable quality of research output. It is for this reason that the article discusses the MRP, its macrophases and the key decisions in each phase in detail.

While the need for uniformly high quality of research output is ubiquitous, the operating conditions in companies on a day-to-day basis are rarely consistent or homogeneous. Consequently, the article also discusses conditions under which researchers modify and adapt the traditional MRP. Additionally, while MR has made admirable contributions to business decision-making, demands for MR to morph into a larger and more comprehensive information system for influencing business outcomes are increasing. Accordingly, the article presents a prototype that has the potential of meeting these

emerging expectations. The article acknowledges that the traditional MRP will continue to play a vital role. But it also urges for a bigger playground where other forms of data, data collection methodologies, and analytical procedures feature equally prominently, sometimes even more.

motivation research

Robert V. Kozinets

Questions such as “Where did Betty Crocker’s maternal appearance come from” or “How was the famous Exxon logo ‘Put a tiger in your tank?’ coined?” or “How did Nestle tried to crack the cultural code and market coffee to the tea-drinking nation of Japan?” or “How did ice cream containers become round?” have answers that are quite surprising, as they are all involved with a very unusual and controversial form of consumer research called *motivation research*, which continues to be influential and contentious to this day.

Motivation research is a term used to refer to a selection of qualitative research methods designed to probe consumers’ minds to discover the deep, often subconscious or latent reasons and goals underlying everyday consumption and purchasing behaviors. Motivation research was the premier consumer research method used in the 1950s, leading to its lasting influence on the areas of advertising and consumer research, as well as on advertising practice. In academic circles, however, the rapid rise of motivation research was followed by an equally rapid decline (Stern, 2004).

Sigmund Freud’s psychoanalytic personality theories provide the foundation for the development of motivation research in marketing. The theory was built on the premise that unconscious or deeply hidden needs and drives underlie all human behavior. Particularly influential are sexual drives and other deep-seated biological ones such as the need for dominance and aggression. Freud’s theory was constructed from his own patients’ recollections of early childhood experiences, combined with an analysis of their dreams, as well as the specific nature of their problems with mental and physical adjustments to their situations. In Freudian theory, these needs are assumed to lie at the very core of human personality and motivation.

Ernest Dichter was trained as a psychoanalyst in Vienna and moved to New York in 1938 (Stern, 2004). He began adopting Freud’s psychoanalytic techniques to the study of consumers buying habits in the 1930s. Until that time, marketing research has mainly

focused on what consumers did – descriptions of their behaviors (see DESCRIPTIVE RESEARCH). These studies tended to be quantitative as well as anecdotal, what came to be commonly known as *descriptive statistical case studies*. Providing a fresh and refreshing change to this, Dichter used qualitative research methods not to describe what was actually done, or even said; instead, he tried to delve deeper into why consumers actually behaved as they did (see EXPLORATORY RESEARCH).

Dichter’s fame quickly spread because of his new approach, engaging presentations, and skilled writing style. The entertaining and usually surprising explanations offered for different kinds of consumer behavior fascinated the advertising and marketing world, particularly since many of these explanations were grounded in sexual motivations. For example, marketers were told that cigarettes and lifesaver candies were bought because of their sexual symbolism. Men, it was claimed, regarded their convertible cars as surrogate mistresses (Dichter, 1964). Before long, almost every major advertising agency in the country had on its staff a psychologist who conducted motivation research studies. Some of Dichter’s more influential and long-lasting insights can help us understand the basic principles of the analysis.

In one set of studies, Dichter describe baking as an essential expression of femininity as well as motherhood. It was also very sensorily fulfilling, evoking nostalgic memories such as the delicious odors that pervaded the house when the mother was baking. Dichter (1964) postulated that, when baking a cake, a woman symbolically linked to the act of giving birth. The most powerful moment of the experience occurs when a product is actually pulled out from the oven, symbolizing the moment of birth. When a woman bakes a cake for a man she is offering it to him as a symbol of her fertility. At the time, the envisioning of Betty Crocker’s appearance was apparently based on Dichter’s analysis of baking as fertility. In our contemporary times, we can only speculate what is symbolized by the baking of a cake by a husband for his wife (Hitt, 2000).

The amazingly long-lived Exxon/Esso logo “Put a tiger in your tank” and its related campaigns had their genesis in another Ernest

2 motivation research

Dichter study (Dichter, 1964). According to Dichter, the automobile allows consumers to convert into reality two powerful subconscious urges. The first is the aggressive urge to compete with, beat, best, and destroy that psychoanalysis finds present as a real force in all human psyches. The second is *Thanatos*, the powerful encounter with mortality, the fear of death. For example the expression “step on it” comes from the desire to feel power. The phrase “I missed hitting that car (or baby stroller) by inches” reflects the profound desire to play with danger, to come close to the edge of mortality. Dichter’s idea was to develop a slogan that allowed the fuel company to tap into consumers’ unconscious aggressive motives for driving a car (Patton, 2002). The outcome emerging from this research insight, added to the creativity of Exxon’s hired advertising copywriters, was an image that mixed control of a wild force with a tamed viciousness: a tank full of striped, feline fury.

And how did ice cream boxes become round? After an analysis conducted for a dairy food company, Dichter (1964) found that ice cream was a type of sexually satisfying, orgiastic food. It melted in one’s mouth providing a extremely sensual and pleasurable sensation. Like mother’s milk, it did not need to be chewed, but invited sucking. It was sweet and creamy, a pure hedonistic pleasure. Its sweetness and richness signify incredible abundance and people eat it as if they wanted it to run down their chins. Because of these aspects of pure abandon and hedonistic excess, Dichter recommended an ancient symbol of limitlessness. The circle, the line without end, the ceaseless pleasure of abundance and earthly delights, was the best packaging for ice cream. Further, the box should have illustrations running around its periphery to show the unending delight of the delicious ice cream within.

This form of analysis may seem foreign and unscientific, and some of these examples might seem overblown and hyperbolic. The fact that motivation research seems strange to us really is not very strange at all. It is based on the premise that we, like all consumers, are not usually aware of the reasons that underlie our behaviors (*see* ETHNOGRAPHIC RESEARCH; EXPLORATORY RESEARCH). One of the reasons we react with embarrassment when we have

these explanations is because they deal with such central, deep-seated needs. As motivation research digs deep into these needs, we gain insights that allow the marketer to better understand the underlying feelings, attitudes, and emotions that concern the use of a product, service, or a brand, or other consumption goods such as experiences and ideas. Perhaps it is therefore no wonder that, although she has had a little cosmetic work done, Betty Crocker is still Betty Crocker, Exxon still puts tigers in our fuel tanks (and in their advertising campaigns), and ice cream containers are still round. As seen later in this article, motivation research, repackaged into contemporary forms, continues to exert a major influence on advertising and marketing practice.

EVALUATIONS OF MOTIVATION RESEARCH

By the early 1960s, marketers began to believe that motivation research was flawed (Stern, 2004). First, because of its intensive nature, qualitative research sample sizes had to be small. Traditional, statistics-driven marketing researchers worried about generalizing the findings of a small group of consumers to the totality of the marketplace (*see* STATISTICAL APPROACHES TO DETERMINING SAMPLE SIZES). Second, marketing researchers also worried that the analyses of projective test and depth interviews were highly subjective (*see* FOCUS GROUPS AND DEPTH INTERVIEWS; PROJECTIVE TECHNIQUES). In fact, it seemed that the quality of the interpretation depended very much on the acuity and even brilliance of the interpretive researcher (however, the same might be true of any technique, such as the detailed analysis and interpretation of sophisticated quantitative data).

Third, critics of motivation research noted that many of the projective tests that were used had originally been developed for purposes of clinical diagnosis of mental illness rather than for studies of marketing or for consumer behavior (*see* PROJECTIVE TECHNIQUES). Consumer behavior studies, however, were interested in finding explanations for the behavior of typical consumers. On the other hand, Freudian theory was developed in an entirely different social

context – nineteenth century Vienna – and applied in the 1950s into postwar America.

Finally, many motivation researchers would inject highly exotic and usually sexual reasons into what seemed to many to be rather prosaic and everyday consumer purchases and behaviors. For example, was it better to sell a man a pair of suspenders as means for holding up his pants, or as a type of protection to help him cope with his castration anxiety? Should a car be sold to a woman as an efficient vehicle or as an impressive substitute penis to help her compete in a world of aggressive men? Marketing researchers concerned with the dignity, reputation, and legitimacy of their scientific field began to question the often rather spicy explanations that were offered by the motivation researchers. It seemed that in the eyes of the motivation researcher, almost any mundane product or service also had a profoundly symbolic – and usually sexual – side. But for many marketing and consumer researchers, it was beginning to seem as though motivation research had forgotten Freud's famous saying that, sometimes, a cigar was just a cigar.

MOTIVATION RESEARCH TODAY

Despite its rocky history and many critiques, motivation research is still regarded as an important technique by marketers who want to gain a deeper understanding into why consumers act in the ways that they do. These insights are often thought to be much more revealing than the information provided by traditional descriptive and quantitative marketing research methods (*see* FOCUS GROUPS AND DEPTH INTERVIEWS). Although the term *motivation research* is most often used to refer to qualitative research that is designed specifically to discover consumers' hidden, tacit, latent, or unconscious motivations, the term can also be used to reference any form of research that seeks to explain why people do things rather than simply describe what they do, or offer correlates to that behavior (*see* EXPLORATORY RESEARCH).

Over time, we have learned that many of the motivations driving consumer purchases indeed are motivated by sexual, dominant, violent, other biologically basic needs identified by Freud. We need look no further than

the worlds of fashion, sports, entertainment, pornography, and video-game production and marketing for examples. The recent boom in design and attention to user-oriented design principles draw our attention to the fact that human motivations to buy and use products and services are indeed complex and social. In fact, because motivation research can often reveal unsuspected consumer motivations that underlie the use of a particular product or brand, one of its main uses in marketing is in innovation. Today, motivation research is popularly employed as a source of valuable, creative, front-end insights that are later quantitatively tested on larger representative samples of consumers. In a competitive global environment in which insight and innovation are keys to success, it is no wonder that motivation research continues to play an extremely important role.

Motivational research has a long, proven track record of being able to help deliver ideas that spawn new products and market categories, to act as a valuable input into the brainstorming of new products and services, to help in repositioning existing brands, as well as to develop new ideas for promotional campaigns. Motivation research offers novel ideas that can be used to penetrate the consumer's conscious awareness by appealing to their needs, fears, dreams, and desires that lie hidden under the surface of their conscious awareness.

By the 1980s, qualitative consumer and marketing research had evolved to encompass a variety of research approaches, including ethnography (*see* ETHNOGRAPHIC RESEARCH), semiotics, CONTENT ANALYSIS, literary techniques, historical methods, discourse analysis, phenomenological methods, and conversation analysis (*see* EXPLORATORY RESEARCH). For some time, the two techniques of depth interview (*see* FOCUS GROUPS AND DEPTH INTERVIEWS) and projective tests (*see* PROJECTIVE TECHNIQUES) were the methodologies most commonly associated with motivation research. The psychoanalytic interview developed in marketing and consumer research, as it did in other social scientific fields, into the "depth" or (later) "long" interview, and the clinician's Rorschach and thematic tests evolved into a variety of projective tasks.

By the 1990s, many of these research approaches had become firmly established in marketing and consumer research. Motivation research can be seen as one step in a series of stages in the development of a vast range of marketing research techniques designed to uncover various facets of people's thoughts, desires, and lifestyles. Although projective tasks are used by researchers today, they are not nearly as common as they were during the heyday of motivation research. Interviews, however, are a staple of consumer and marketing research, whether in their academic one-on-one format, or in the focus group interview format, which is extremely popular in marketing research practice (see FOCUS GROUPS AND DEPTH INTERVIEWS). In the first years of the twenty-first century, these methods, which had their inception in motivation research, continued to make gains in enhancing our understanding of consumers' deeper motivations, meanings, and understandings of the world. Through its more detailed, complex, and subtle social analyses, motivation research is alive and well and still very much with us. By emphasizing the less obvious aspects of consumer behavior, it has helped marketing recognize some of the important forces driving consumer culture.

Some of the qualitative research techniques used in the original motivation research have been developed and are now in common use, particularly among advertising, marketing, and marketing research practitioners. In the following section, we present an introduction to some of these tools that may be useful in research.

MOTIVATION RESEARCH TOOLS AND TECHNIQUES

In contemporary marketing research, there are a number of qualitative research techniques used to delve into customers' unconscious hidden motivations. These techniques draw their lineage directly from motivation research. They include projective tests and tasks, metaphor analysis, storytelling, word-association tasks, sentence-completion tasks, picture generation, and also photo sorts (see EXPLORATORY RESEARCH; FOCUS GROUPS AND DEPTH INTERVIEWS; OBSERVATION METHODS;

PERSONAL OBSERVATION; PROJECTIVE TECHNIQUES). Marketing researchers such as Gerald Zaltman and Clotilde Rapaille are new practitioners of the craft of motivation research who pick up, develop, and make contemporary the approach initially popularized by Ernest Dichter.

Thematic apperception test and other projectives.

The thematic apperception test was developed by Henry A. Murray and Christiana D. Morgan at Harvard University during the 1930s to explore some of the motivating forces underlying personality. It is a picture interpretation technique that uses a standard series of 30 pictures about which the research subject is asked to tell a dramatic story. The pictures themselves are open-ended yet provocative, showing, for example, a young boy contemplating a violin that sits on a table before him.

For a marketing research example, consider the hypothetical research we might conduct for a new cold medication. In this research, there would be an image of a middle-aged woman in a bathrobe looking into a mirror and a caption underneath it saying "She looked into the mirror that morning and realized that she had a cold." When we show this picture to women, what might we hear? As researchers we would probably discover that middle-aged women consider their lives to be fast paced, full of obligations, and socially active. The discovery of a cold abruptly disturbs the pace of their lives. An advertisement that could result from this projective research might show an attractive, busy, middle-aged woman walking down a busy street. She sneezes and then, suddenly, all the motion around her stops. She opens her purse, takes out the cold medication, takes it, smiles, and then her life speeds up to its previous rapid pace. By providing such an image in advertising, the marketer is to symbolize that they understand the lived experience and social world of the consumer. This image-based positioning builds strong emotional ties between the brand and the consumer.

Metaphor analysis. Metaphor analysis is a method based upon providing visual images to consumers, or having them collect their

own images, and then using these images for projective tasks in which they compare and contrast products, services, or brands to the various images, and the images to one another. The analytic goal of metaphor analysis is to generate guiding analogies providing a deep sense of understanding of how consumers relate to a particular product, category, or brand.

Gerald Zaltman, Professor Emeritus at the Harvard Business School, has popularized this method in recent years. His approach, which he terms ZMET, or the Zaltman metaphor elicitation technique, is based upon many of the same fundamentals as classic motivation research. Zaltman (1996) offers the following founding principles for his metaphor test: the nonverbal and unconscious nature of most social communications, the image-based or imaginary nature of most human thought, the centrality of the form of metaphor to human thinking, the embodiment or bodily nature of cognition and thought, the linkage of reason, emotion, and experience and the assumption that deep structures of human motivation can be accessed through projective-style research (*see PROJECTIVE TECHNIQUES*). The relation of the body, emotions, and hidden unconscious motivations to the projective task of marketing research relates this work directly to motivation research.

In the ZMET test, consumers are either asked to collect a number of images that represent their thoughts and feelings about a product, service, or brand, or they are provided with these images in various forms. The forms can be clippings from a magazine or specially designed graphics and photographs that they select from the computer screen. Research participants are given the focus of the research a week or more in advance of the actual interview. They are encouraged to ruminate and think deeply about the topic of the assignment and, if relevant, about their selection of photographs and images. The research question must be carefully considered in order to focus the response of the consumers. Considerations may include their opinions of a particular company or brand, their experiences of a purchase setting or a buying process, their use of a service or product, or how they feel about a certain concept. Participants are also directed not to choose photographs that literally represent a product or service. For

example, if the research topic is mobile phones, the research participant would be asked not to select any actual photographs or graphics of mobile phones. Forcing the research participant to choose photos that indirectly relate to digital cameras activates an analogical style of reasoning that, it is assumed, can help reveal latent feelings, thoughts, and motivations (Zaltman, 1996).

The interview is approximately two hours in length and consists of guided questions regarding the images chosen by the consumers to answer the focused research question. As the interview progresses, participants are asked for their opinions regarding other senses that might express their feelings and thoughts. The researcher's main task is to attempt to elicit as many rich metaphors from the participant's experiences and memories as possible. The idea, according to Zaltman (1996, p. 15), is to allow "deep, latent ideas to emerge as well as for the expression of the wide range of relevant ideas." Increasingly, the ZMET and other metaphor-based techniques have incorporated advanced mapping and diagram-drawing techniques to analyze and present the findings of their research, as well as digital graphical design and even creative animations with voice-overs. The ZMET technique has been very successfully adopted and used by the top corporations in the world, from Coca Cola and Procter & Gamble, to Walt Disney, Mercedes-Benz, Bank of America, Microsoft, and Chevron.

Storytelling. In the method of guided storytelling, consumers tell real-life stories about the meanings or uses of products under investigation. Although this technique is related to depth interviews, it is considered to be a distinct form of research. Often, the storytelling method asks research participants to imagine and relate stories relating to their own product or service usage. Another application of the storytelling methodology requires subjects to imagine a story involving another person. So, for example, people who have a fear of tall buildings would be asked to imagine and then tell a story about why some people are afraid of tall buildings. In this way, the storytelling process ameliorates people's own anxiety, embarrassment, and social-censoring mechanisms. Doing so, people

will be less likely to censor their own apprehension about heights and to offer an accurate portrayal (see EXPLORATORY RESEARCH).

As a form of motivation research, the storytelling method seeks to plumb the depths of consumer motivations. For example, Kimberly Clarke used a storytelling method in order to study current perceptions about diapers (Lieber, 1997). They found that using this research method, the parents actually considered that diapers were a type of clothing related to a particular stage in the child's development. If their child wore diapers for too long, the result was that the parents became distressed and embarrassed because they viewed it as a failure. They felt that they had not toilet trained their children properly and that this lack of success was obvious from the children wearing the wrong apparel for that particular stage in their life. Using the data from this storytelling study, Kimberly-Clark introduced its new Huggies Pull-ups training pants. These training pants introduced a highly successful new category into the US diaper industry.

Word-association and sentence-completion tasks.

In word-association tests, research participants are presented with words one at a time, and then asked to respond with the first word that comes to mind, for example, "What is the first word that you think of when I mention the word or category coffee?" In a sentence-completion task, respondents are asked to complete a sentence upon hearing the opening phrase. For example "People who drink Starbucks are ..." or "A Starbucks latte reminds me of..." These related methods can be very useful in determining consumers' associations with existing brand names, eliciting related choice sets, as well as determining associations with new brand names that are being considered and that are currently under development.

An entire web site has been devoted to creating word clouds based on people's reactions to brand names. It is called *Brand Tags* and is available at <http://www.brandtags.net>. As can be readily seen, by clicking on almost any brand name, there is a very wide assortment of responses. For example, the word cloud associated with Starbucks includes not only strong, burnt, green,

and trendy but corporate, mermaid, addictive, ubiquitous, and overpriced.

Picture generation. Marketing researchers can also use visual images to study consumers' perceptions of various brands. They can use an analysis of consumers' guided drawings or doodles to help understand consumer perceptions, and use that understanding to brainstorm new strategies for advertising. Consider some hypothetical research on coffee. Research participants were asked to draw pictures of the typical drinker of Maxwell House coffee. These drawings might elicit drawings of old-fashioned, chubby females wearing frilly aprons. When asked to draw pictures of Starbucks drinkers, the drawings might show a series of slim, cool, "with it" women wearing high heels and miniskirts. For a company like Maxwell House, these findings might provide important input about the dire need to reposition its product to seem more in tune with the times.

Photo sorts. In photo sorting tasks, respondents receive stacks of photos depicting various events and are asked to select the pictures from the set that best portrays or captures some particular element that the researcher is interested in investigating. In a photo-sort study that was conducted by an advertising agency for Playtex, the manufacturer of bras, research participants received a stack of photos that portrayed many different types of women wearing many different types of clothing. First, the research participants were asked to choose pictures that represented the typical user of Playtex bras. They chose overweight, old-fashioned, big-breasted women (O'Shaughnessy, 1995, p. 437). These women, who were Playtex users themselves, were then asked by the researcher to select the pictures from those that best captured their own self images. Although many of the respondents may have been overweight, full-breasted, and old-fashioned in appearance, they selected photos that showed physically fit, well-dressed, and independent-looking women. The advertising agency then advised Playtex to stop stressing the comfort of its bras in its advertising campaigns and, instead, to design a new campaign that showed thinner and sexier

big-bosomed women under the slogan “the fit that makes the fashion.”

CONTEMPORARY MOTIVATION RESEARCHER: CLOTAIRE RAPAILLE

One of the great contemporary practitioners of an updated form of motivation research is Clotaire Rapaille, a French-born psychoanalyst and medical anthropologist whose methods for mining covert motivations have compelled many Fortune 500 companies to spend massive amounts of money on his brand of “culture code” marketing research. Rapaille’s research is based upon a sociobiological idea of “imprinting” that originated with studies of geese:

the combination of experience and its accompanying emotion create something widely known as an imprint, a term first applied by Konrad Lorenz. Once an imprint occurs, it strongly conditions our thought processes and shapes our future actions. Each imprint helps makes us more of who we are. The combination of imprints defines us... every imprint influences us on an unconscious level. Rapaille, 2006, pp. 6–7.

To explain how he uses the notion of imprinting in his research, Rapaille gives the example of working with Swiss food giant Nestlé trying to sell instant coffee in Japan. He discussed how he gathered groups of people together to discover how they imprinted their perceptions of coffee. He scheduled a 3 hour session with each group of research participants. In the first hour, he queried the participants about coffee usage as if he was an alien from a different planet who knew absolutely nothing about coffee. In the second hour, he had them sit on the floor using scissors and piles of magazines to make a collage of words that represented their impressions of coffee. His intuition was that these visual images would help them to express stories about coffee that could give him further insights into coffee consumption.

For the final hour of his investigative research, Rapaille asked participants to lie on the floor with pillows, put on soothing music, and asked them to relax. He spoke to them about the past, taking them from their adult years to their teen years to a time when they were young. At that point in the guided meditation, he asked them to think about

coffee and to recall their earliest memory of it. He sought to elicit the very first time that they consciously experienced coffee as well as their most significant memory of coffee. Rapaille says that he learned that Japanese people had only a very superficial imprint of coffee and many had no imprint of it all (Rapaille, 2006).

His conclusion to Nestlé was that the current strategy of attempting to switch to drinkers to coffee was bound to be a failure. Nestlé instead needed to begin by giving coffee a meaning, in other words, offering up an imprint for the Japanese market (Rapaille, 2006). Nestlé began acting on this advice by creating desserts for children with coffee flavors but without caffeine. Because they were gaining a sweet-tasting coffee experience as their first imprint, Japanese youth gained a very positive first impression. The idea was that this impression and imprinting would follow the youth through their lives. Although cause and effect are difficult to measure in such complex cultural circumstances, coffee sales in Japan have steadily risen and now approach up to a billion pounds per year.

Betraying his psychoanalytic roots, and, of course, in the world of marketing research, the path from Freud to Dichter being rather short, Rapaille considers that he reveals the “reptilian” part of the brain, which is the home of violence, strong smells, violence, sex, and primal emotions (Hitt, 2000; Rapaille, 2006). According to Hitt (2000), Rapaille typically begins a marketing research session by leading a group of about 20 people through a series of word-association games. After writing words on a board, the researcher then asks the group to identify themes that unite the words. He then has them tell stories based on the concepts that have been written on the board. The idea behind this technique is to generate a number of little stories. And as in the concluding part of Rapaille’s (2006) investigative research, the marketing research session involves having the research participants lie on the floor, with blankets and pillows, while repetitive and relaxing music plays for about 20 minutes to calm down the active mind. At this point, the researcher seeks to take the room full of participants back to their earliest memory of a product or category. After talking to them, he asks them to write down the story of their earliest and their most vivid memories relating to

the product or category. These recollections then become the data that the researcher uses to find deep-seated, hidden, archetypal associations. Of course, we have no proof that these memories are actually valid memories of childhood experiences. Most likely, they are constructions that the participants rearrange in the present moment in order to fulfill the requirements of the research. Nonetheless, just like other types of impressionistic research gathered through motivation techniques – a collage, a completed sentence, a creative story told about an ambiguous picture – they become the basis of researcher insights in this method.

Reading through examples of Clotaire Rapaille's marketing research conclusions, one cannot help but be struck by its similarities to Dichter's motivation research. Rapaille considers that his research decodes the existing codes behind product categories discovering people's true product meanings and motivations for use. His colorful style, powerful and simple conclusions, creative metaphors, and usually biologically rooted bases for explanation evoke the spirit of motivation research. Consider as a final example, the way that Rapaille discusses the difference between the way that French and American people understand the category of cheese:

The French code for cheese is ALIVE. This makes perfect sense when one considers how the French choose and store cheese. They go to a cheese shop and poke and prod the cheeses, smelling them to learn their ages. When they choose one, they take it home and store it at room temperature in

a cloche (a bell-shaped cover with little holes to allow air in and keep insects out). The American code for cheese, on the other hand, is DEAD. Again, this makes sense in context. Americans "kill" their cheese through pasteurization (unpasteurized cheeses are not allowed into this country), select hunks of cheese that had been prewrapped – mummified, if you will – in plastic (like body bags), and store it, still wrapped airtight, in a morgue also known as a refrigerator. Rapaille, 2006, p. 25.

marketing research proposal

Gaurav Bhalla

INTRODUCTION

Imagine you are the Director of Brand Strategy and Communications at McDonald's corporation. You are aware that obesity, especially child obesity, is fast becoming a major health and social issue. You have a copy of the book *Fast Food Nation: The Dark Side of the All-American Meal* (2001) by investigative journalist Eric Schlosser, but have not read it from cover to cover. However you have seen the movie *Fast Food Nation*, based on the book. As a marketing and strategy professional, you know that McDonald's cannot ignore this growing trend. You and your colleagues firmly believe that the company should proactively signal to its numerous stakeholders – consumers, franchise owners, school teachers, nutritionists, media, legislators, and so on – that McDonald's is sensitive to the social and health implications of obesity and that it is genuinely interested in playing its part to help combat its growing menace.

However, while you are aware of the macro aspects of the problem, you lack a granular understanding of what is actually happening in the marketplace. You have numerous questions on the implications this growing concern about obesity has for McDonald's.

- What are stakeholders' specific attitudes toward the phenomenon of obesity and toward food companies like McDonald's, Kraft, Kentucky Fried Chicken, Hershey, Nestle, and so on?
- Do stakeholders believe that McDonald's is responsible for contributing to obesity? Is it a global perception, or is it localized in some countries?
- Do stakeholders apportion the blame on both the company and its menu offerings? If yes, is it possible to separate the two components?
- What are some of the behavioral implications of stakeholders' perceptions?
- Are there specific initiatives that McDonald's can undertake to neutralize negative-obesity-related perceptions that stakeholders may have against McDonald's?

Experience has taught you that rather than tackling these questions yourself it is best to call in the market(ing) research (MR) department and have them commission a program of formal information gathering to help fill the gaps in your understanding. So, you invite the MR lead assigned to your department for a meeting.

Now, let us switch our attention to the MR department. Contemporary management practice prides itself in data-driven decision making. One of the tools that companies use to gather and disseminate market data is formal MR. Accordingly, it is standard practice for companies like McDonald's, Kraft, P&G, Microsoft, Citi, Mercedes Benz, Tesco, and so on, to have formal MR, or customer/competitive/market insight departments. Traditionally, MR departments of client companies seldom execute MR projects, studies, or programs themselves. They call on specialist providers of MR services to do so. Table 1 contains a list of leading specialist MR providers, ranked by their most recent revenues.

It is here that we encounter the MR proposal (see also SURVEY RESEARCH). To begin the information-gathering activity, client companies usually issue a request for proposal (RFP). How many and which MR service providers are invited to submit a proposal varies from one client company to another (discussion on RFP practices is beyond the scope of this article). In its essential form, an RFP is an invitation to the specialist MR firms, requesting them to submit a detailed proposal, explaining how they would go about meeting the requirement of the RFP, such as data collection, sampling, timing, presentation of results, execution, and pricing. The RFP may be issued by MR professionals, those who have direct responsibility for coordinating the information-gathering activity with the MR firm, or by centralized sourcing and procurement departments, like the Purchasing Department. This article will assume that the RFP is issued by the MR department, allowing for greater flexibility of dialogue and presentation of ideas.

An MR proposal is not merely a compliance document, complying with all the requests and demands made in the client's RFP. It is also a sales document. A proposal is an opportunity for the MR firm to make a strong case for why it should be awarded the project. It is this

4 marketing research proposal

balancing act – balancing the technical aspects of how it will execute the project, with the selling aspect of why it should be awarded the project – that makes writing an MR proposal an art form. Accordingly, this article will discuss the MR proposal not as a recipe, but in terms of a framework that we turn to next.

ANATOMY OF AN MR PROPOSAL

Table 2 presents the anatomical structure of an MR proposal.

Broadly speaking, the structure of an MR proposal mirrors the MR process, as discussed in popular text books (Kumar, Aaker, and Day, (2009); Malhotra, 2007; Zikmund and Babin, 2007). However, no single framework, no matter how comprehensive, can ever capture all the different ways in which an MR proposal can be put together. Accordingly, Table 2 should be viewed as a prototype, around which the reader can experiment, if necessary. The next several sections will discuss the individual elements in detail.

COVER PAGE AND TABLE OF CONTENTS

As noted above, an MR proposal is both an information and a sales document. Consequently, the cover page should not be viewed as a mere functional necessity. At a minimum, it should be used as a signaling tool and to generate positive momentum from the outset. Perhaps clients are not going to judge a proposal by its cover, but they are definitely going to be unimpressed by the one that does not even try to stand out. Regardless of whether the clients view the proposal as an e-document, or as a printed document, the cover is what they will see first – and first impressions do count.

At a minimum, the cover page should have the following characteristics:

- *Customization*: it should be customized for the client, company, or SBU, inviting the proposal.
- *Specific title*: it should have a clear and tell tale title that offers a window to what the reader can expect from the proposal; example, saying testing service concepts for home-based businesses, is better than merely saying concept test MR proposal.

- *Visual appeal*: we live in an image-rich world; a relevant image, related to the theme of the proposal could greatly enhance the visual appeal of the MR proposal.
- *Date and contact details*: the name and contact details of the primary contact and the date of proposal preparation communicate service friendliness; the reader does not have to shuffle papers to reach the relevant person when they have a question, or need more details.

The table of contents (TOC) is an essential housekeeping chore, not glamorous, but contributing significantly to the overall efficiency and service friendliness of the document. A proposal could be anywhere between 15 and 25 pages long, or longer, depending on the format being used – Word, PowerPoint, or PDF. Searching for relevant content could be very inefficient and time consuming without a TOC page. Imagine a scenario where the client is reading the third of five invited proposals. Assume that the client is intrigued by the proposed research design and wants to revisit the first two proposals to make comparisons. A TOC page will make it easier for the reader to revisit

the relevant sections of the first two proposals without unnecessary shuffling and searching.

EXECUTIVE SUMMARY

An MR proposal is usually distributed to several key-decision makers within the client company. Not all of them are likely to be motivated to read every page of the proposal. An executive summary (ES) is an indispensable tool for those who want to get a macro understanding of the contents of a proposal without having to read every single page.

An ES should be written assuming that the person reading it will read no other page in the proposal. Well-written executive summaries usually have the following defining characteristics:

- *Completeness*: an ES should be complete, it should cover every single element referred to in the TOC and should read like a stand-alone document.
- *Specificity and concreteness*: there is not enough space in an ES for adjectives and qualifiers like state-of-the art, large, comprehensive, and so on. It is far better to say that 1500 respondents will be contacted, a 20-minute Internet survey is planned, and so on.
- *Brevity*: maximum one page, preferably shorter.

BACKGROUND AND SITUATION ANALYSIS

MR is a means to an end – it is commissioned to provide information inputs to decision making. Communication between the client commissioning the research and the service provider preparing the proposal is positively served when there is a mutually unequivocal understanding of:

- the decisions most likely to be influenced by the MR project and
- the context within which the decisions are most likely to be made.

The role of this section is to demonstrate this mutually unequivocal understanding of the context and the application.

A common mistake encountered at this stage of the proposal is the tendency to merely reproduce the text contained in the RFP in different words. A mere restatement does not demonstrate an understanding of the client's business situation or decision challenges. To illustrate, one of the biggest casualties of the current financial crisis has been the erosion of consumer trust and confidence in large financial institutions. Now, if you as an MR service provider are hired by clients like Citi or Bank of America to help them regain lost consumer trust, you are more likely to succeed if you display a crisp understanding of the dynamics that led to the erosion of trust. Merely restating that the MR proposal is being written to help clients like Citi and Bank of America regain lost trust of the consumer is not going to inspire much confidence in the reader.

This is a stage-setting phase of the proposal. By definition, therefore, the understanding reflected at this stage should have a clear connection with the content to follow. The content of this section should materially influence research objectives and research design to be presented later. In the absence of such continuity, the holistic-integrated properties of the proposal are likely to be compromised.

It is not uncommon for the MR service providers to conduct some desk research at this stage to reinforce or refine client perspectives reflected in the RFP. It is highly recommended, as it improves the overall thinking about the decision problem and the information to be collected. Continuing with the erosion of consumer trust example, desk research may suggest that experts are recommending a return to neighborhood banking principles. If the client's RFP is focused exclusively on exploring mass media initiatives, you may want to help modify the client's perspective by recommending community-based initiatives as well.

RESEARCH OBJECTIVES

As stated above, when discussing the mini-case study on obesity, client companies commission MR studies because they want relevant information to make better business decisions. MR service providers write MR proposals to indicate how relevant data and actionable insights will

be provided. Research objectives help ensure that these two perspectives converge. Before the client spends any money, research objectives should help answer the question – *if we execute this study, will we actually get the information we are looking for to help us make better decisions?* Additionally, research objectives also help to audit project performance – did the MR service provider actually deliver on all that the client had contracted for?

As the development of research objectives requires translating managerial information needs to MR tasks, judgment, and skills which come into play in determining the best way to structure the data collection task. What makes it even more challenging is that usually there is no one best way to execute the MR study. A few examples of how business questions were translated to research objectives are given below. It is important to acknowledge that different researchers may have their own points of view on what is the best way to answer the managerial question posed, and may disagree with the recommendations presented below.

- A snack food company wanted to introduce line extensions for its chips and crackers line. The research response to this marketing question was to research salty snack concepts that would meet snacking needs between the hours of 3 p.m. and 6 p.m. (postlunch, predinner).
- Should an insurance company continue to pay a hefty annual amount for sports sponsorship, in this case, an annual tennis tournament? This business question was researched by modeling the return on investment (ROI) on the sports sponsorship expenditure using the customer equity and customer life-time value framework.
- Are all shoppers identical? How do they differ in terms of their planning, their frequency of shopping, their average expenditure the assortment of the items they shop for, and so on? This marketing question was researched by conducting a nationwide shopper segmentation study.

No client or MR service provider has unlimited resources to conduct an MR project. This poses a further challenge to the development of

research objectives. The implications of limited resources are obvious – MR professionals need to make trade-offs – in terms of what should be included in the proposed study and what should be left out. This is not always easy, as business and marketing issues are usually influenced by many factors. Trade-offs can be compounded if the research is catering to the information needs of multiple stakeholders and/or if the client is insisting on making the research project carry a heavier data collection load than it is designed for.

Something that is often overlooked in the development and articulation of research objectives is stratifying them as *primary* research objectives and *secondary* research objectives. While not all MR proposals need to consider this stratification, keeping this distinction in mind does help in apportioning emphasis and scarce data collection resources, when the need arises.

For example, a secondary objective in researching patients' treatment practices for migraine could be the actual usage in the past 90 days of alternate therapies, home-made remedies, and over the counter OTC drugs for the treatment of the headache. The secondary objective makes good business sense, because usage of Rx therapies as a class may decline if the usage of alternate, homemade, and OTC therapies increases. This could affect all brands in the category, regardless of how dominant a brand is.

RESEARCH DESIGN

In its essence, this section addresses the fundamentals of data collection – how will the MR service provider collect the data, why the provider thinks that it is the best way to do so, and which instruments will be used in the data collection process? Hopefully by now the reader has sensed that the various elements of the proposal are like sequential legs of a relay race, with the preceding section handing off the baton to the succeeding one. The previous leg of the relay, or section, discussed what research objectives will be addressed by the study; this leg of the relay, or section, will discuss which data will address those research objectives and how will those data be collected (*see also* MARKETING RESEARCH PROCESS).

This section should discuss at least three subelements:

- *conceptual framework*: the overriding plan, thinking, framework, and concepts that will guide data collection.
- *scope of research*: establishes the domain and limit of data collection, especially as it applies to geographies and populations.
- *line of inquiry*: the type of data that will be collected, the range of topics that will be covered, and the sequence in which they will be addressed.

Conceptual framework. One of the strongest differentiators between the good research and the unsatisfactory research is the fit between the managerial questions posed by the client and the research solution provided by the service provider. For example, if the question posed by the client is intrinsically longitudinal in nature as in – *how do above the line and below the line marketing expenditures influence brand equity* – then offering a cross-sectional solution will not help, as it will not take into account lagged effects of marketing expenditures. Accordingly, it is essential that the discussion in this section proceeds in a macro-to-micro fashion, where the overall approach is discussed before proceeding to a discussion of specific micro details. Additionally, to the extent possible, details should also be provided about alternatives that were considered and rejected, along with the reasons underlying the preference for the recommended alternative.

An example of macro-to-micro thinking in navigating the research design and conceptual framework follows.

- Address first the overall recommendation, for example, qualitative research, quantitative research, or some combination of the two. If qualitative research is recommended, then give reasons how the qualitative phase will add value and why it is necessary; if not recommended, explain why not necessary or useful.
- Unless, the RFP explicitly asks for an MR proposal for qualitative research, if you are not considering a quantitative research component, you should explain why you feel

qualitative research alone will be sufficient in addressing the client's information needs.

- Once the macro aspects of the design have been presented, the discussion should proceed with a discussion of design choices within what is being recommended. For example, if qualitative research is recommended, is the preferred framework in-depth interviews, focus groups, or some form of observational research, like ethnography? As before, pros and cons should be presented in support of your recommendation.
- Similarly, if quantitative research is recommended, will the framework be descriptive research, predictive research, experimental design, or modeling? Again, reasons should be provided in support of what is being recommended.
- For both qualitative and quantitative research designs there should be a discussion on the platform that will be used for data collection, whether in-person, telephone, or Internet.
- Once the above issues have been addressed, the discussion can proceed with further micro details concerning number of interviews, interview length, type of experimental design, types of data to be collected, and so on.

The advantage of this systematic macro-to-micro approach is that at all times the reader has an excellent understanding of the thinking and assumptions guiding the proposal writer's recommendations. The client may not agree, or may have other opinions on what is the best approach, but at least they will understand fully the proposal writer's intentions.

Let us illustrate the above discussion with a mini-case study involving a customer-satisfaction study.

A cell phone handset manufacturer wishes to conduct an MR study to identify key drivers of customer satisfaction from individual users of cell phones. If the research provider has to deliver on what is expected, the client and/or company A must have a relevant and updated list of satisfaction drivers before measurement can begin. Right away a decision needs to be made. Is the available list of attributes good enough, or

do we need fresh qualitative research to refresh the list? Once that decision has been made, we then need to decide what framework will be used to determine whether or not a driver is key, and which drivers are more important than others. Let us assume that the research provider is leaning toward an importance–performance framework, because in their experience the four-quadrant approach is an effective tool for communicating with marketing decision makers. Once a decision has been made to use the importance–performance framework, additional questions – stated importance or derived importance; first-hand experience of performance or perceived performance – will have to be answered. If the researcher prefers the derived-importance approach, a case should be made for it, including some discussion on why the stated importance approach will not perform as well. Following this, the researcher can discuss issues related to types of attributes, type of data, rating scales, and analytical techniques.

The nested macro-to-micro approach illustrated above has definite merits. It helps make the thinking of the proposal writer visible to the reader. It also ensures that the proposal writer has not made any unwarranted assumptions, such as the list of drivers is current and does not require updating, or omitted any relevant details.

Scope of research. Once issues related to how data will be collected (*see also* WEB SURVEYS) have been articulated, it is time to discuss which geographies data will be collected in and from which respondent populations.

In today's globally interconnected world, it is dangerous to assume that research projects will be conducted in single homogenous geographies. In Europe, Asia, and Australasia, research is routinely conducted in several different markets (read as countries), each with different respondent, consumer, and language characteristics. The increase in minorities (Hispanic, Black, Asian Indian) makes geographic homogeneity a dangerous assumption, even in the United States, even though it is one single country.

This section of the proposal should explicitly address issues related to geography of data collection, languages in which data will be collected, and populations that will be included/excluded from the study. A sampling of issues that should potentially be discussed in this section follow:

- If the study is to be executed in different geographies/countries, will the questionnaire be translated and administered in the country's spoken language? Details should be provided on how this will be achieved.
- Even if the questionnaire is administered in English, as in UK, India, Hong Kong, and Australia, will expressions and rating scale descriptors be adapted for different environments, or will they remain the same?
- Which populations will be included in the study? Returning to the snack food line-extension study, discussed earlier, will respondents be drawn from the general population, from the population of respondents who snack any time of day, or from the population who snack postlunch only?
- If several populations are to be included in the study – say physicians, nurses, and patients in the case of a pharmaceutical drug study – will the same data collection instrument be used for all populations, or will it be adapted? And if adapted, how? Which aspects of data collection will be common and which unique?

Line of inquiry. A line of inquiry indicates to the reader the type of data that will be collected and the sequence in which they will be collected, without getting into the specifics of questionnaire design and question wording. The line of inquiry can play a key role at this stage because it neatly captures the full range of preceding discussion on managerial information needs, research objectives, and research design.

To recount, by the time we get to this stage of the proposal, there should be agreement on which managerial issues we are trying to address, the type of MR data that will best meet the client's information needs, and how best to collect the relevant data. Given this background, the research executive preparing the proposal should be able to specify the types of data to be collected and the sequence in which the researcher thinks they should be collected.

Let us illustrate this with the help of the snack line-extension case study presented earlier. To recap, an experimental design was suggested to help collect the data. Let us assume that the MR executive preparing the proposal disagrees with

the author and prefers instead a survey-based approach. On the basis of the data to be collected by the survey, the executive develops a line of inquiry, presented in Figure 1.

The line of inquiry makes a valuable contribution. It states clearly the data that the proposed study will collect and the sequence in which they will be collected. It also enables the client evaluating the proposal to determine whether any data that should be collected is missing. For example, on reviewing the document, the client may feel that product/brand substitution data are missing; namely, which snack foods and/or brands, if any, will be replaced by the proposed concepts. The client feels that these data should be included in the line of inquiry. Additionally, assume the client is not totally comfortable with each respondent evaluating only two concepts. Why not three? Surely, the respondents can evaluate three concepts without

excessive respondent fatigue or without excessively increasing the interview length. Our client and MR service provider preparing the proposal can now have a focused discussion on these concerns, something that would not have been as easy in the absence of a well-documented and articulated line of inquiry.

ANALYTICAL PLAN

The analytical plan (AP) plays a key role in drawing inferences and insights from the data collected by the MR project. The AP has an intimate link with the research design, as specific analyses require very specific data inputs. To illustrate, for the customer satisfaction case study presented in the previous section, once the set of key drivers is determined and importance-performance data are collected, some analysis will have to be conducted to identify the key drivers of customer satisfaction. If the

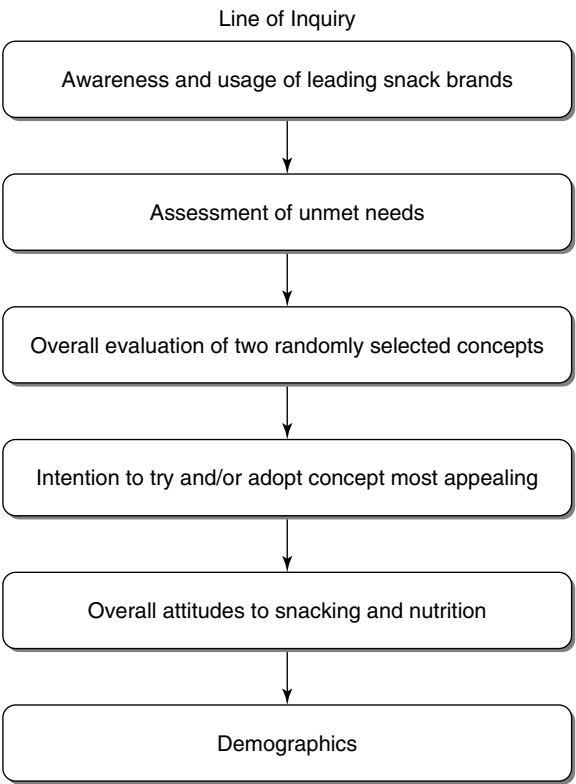

Figure 1 Line of inquiry.

research executive wishes to conduct ordinary least squares, regression to determine which drivers are key, then it is necessary to ensure that interval level data are collected for both sets of independent and dependent variables. If instead of interval data the researcher decides to opt for categorical or check-box data, then the choice of analytical technique will have to be adapted and modified (*see also* UNIVARIATE TECHNIQUES, EXPERIMENTAL DESIGN, ANALYSIS OF VARIANCE AND COVARIANCE, CLUSTER ANALYSIS, EXPLORATORY FACTOR ANALYSIS, MULTIDIMENSIONAL SCALING OF PREFERENCE DATA, DISCRIMINANT ANALYSIS FOR MARKETING RESEARCH APPLICATIONS, MULTIPLE REGRESSION, STRUCTURAL EQUATION MODELING).

Research design and AP are the two sides of the same coin – the former enables the latter. In fact, in some cases the research design virtually handpicks the AP. Longitudinal analysis of advertising effects on sales suggests that the AP will rely heavily on time series or econometric techniques. Similarly, experimental research designs rely very heavily on ANOVA (analysis of variance)-based techniques to quantify the influence of main effects and interactions between the design variables. However, in most cases the researcher does have discretion, in terms of the types of data to collect and consequently, the types of analytical techniques to use. For this reason, the MR executive preparing the proposal is well advised to consider the research design and the AP as a set of interlinked decisions, rather than as two separate decisions.

A few cautionary statements, observations, and myths concerning analysis and APs are presented below:

- Most studies collect a mixture of different types of data – nominal, ordinal, interval, and ratio. The AP should cover proposed analyses for all types of data collected.
- Frequently, analysis is assumed to mean complex or multivariate statistical analysis only. However, analysis refers to all operations performed on the data to make sense of it, including simple summarization and cross-tabulation procedures. All analyses, simple or complex, should be discussed in this section.

- Often, it is assumed that analysis can only be performed on quantitative data. That is incorrect. Qualitative data can and should be analyzed using formal analytical procedures (Miles and Huberman, 1994). Techniques likely to be used to analyze qualitative data should also be discussed in this section.
- Modeling is a common noun for a variety of techniques that depict the structural relationships between the data. If the MR proposal suggests modeling as part of the AP, details should be provided on the type of model that will be developed (linear, nonlinear), data inputs to the model, and statistical techniques that will be used to estimate relationships between the data inputs.
- On most occasions, MR service providers will use off-the-shelf software, like SAS, SPSS, and so on to analyze the data. If the service provider submitting the proposal intends using proprietary software or techniques, details should be provided to make the recommendation as clear as possible (of course, without divulging proprietary details). Black-box approaches, which require the reader to operate on blind trust, may make it difficult for the client to evaluate recommendations made by competing proposals.

LOGISTICS AND EXECUTION

This section deals with execution details, such as

- How many respondents will be interviewed?
- How long will each of the interviews last?
- What procedures, if any, will be followed to ensure that the data collected are clean, reliable, and valid?
- How long will the entire study take – from start to finish?

Three topic areas should be covered here:

1. Sample design and sample size.
2. Quality control checks.
3. Project schedule and timing.

The author's preference is to organize the discussion on all execution elements in one section. However, depending on the preference of the executive preparing the MR proposal, it is possible to cover sample design and sample size in the research design section, while discussing populations and subpopulations to be researched.

Sample design and sample size. If the proposal plans to use specialized sampling plans, like random digit dialing (RDD), two-stage sampling, or quota sampling, then an explanation should be provided covering both design and execution details (*see also* SAMPLING TECHNIQUES, NONPROBABILITY SAMPLING; PROBABILITY SAMPLING). As recommended in the research design section, a macro-to-micro approach is very helpful here as well. An example of the recommended macro-to-micro approach in the context of the snack food concept study presented earlier follows:

- *probability* sampling is preferred to *nonprobability* sampling, as greater precision is required to forecast trial and adoption of winning concept;
- within probability sampling, *stratified sampling* is preferred as three subpopulations need to be interviewed – heavy users, light users, and category nonusers;
- stratified sampling *disproportionate to size* is preferred to give a heavier weight to heavy users; if proportionate to size used, we may get more light users and nonusers than needed.

The sample size should be presented for the total study and for each sampling subgroup. Continuing with the above example, the proposal may recommend a total study sample of 1500, split into the three subgroups as follows – 800 heavy users, 450 light users, and 250 nonusers.

In addition to a discussion on sample design and size, *sampling frame* should also be mentioned. How will the respondent's be selected? Will they be drawn from a panel, or will they be selected from lists purchased from list vendors? If the sampling design is to live up to its promise, the sampling frame must play its part; poor sampling frames, no matter how

elegant or sophisticated the sampling design, will not yield the quality of data hoped for.

Quality control checks. All MR studies have two types of errors, sampling error and nonsampling error. Sampling errors can be controlled with appropriate research designs; nonsampling errors, on the other hand, can only be controlled by paying meticulous attention to process and detail.

Implementing quality control procedures should be standard practice no matter how skilled or experienced the researcher or the service provider is. A few must-do quality control checks are presented below:

- Often clients will ask service providers to borrow data collection inputs from other sources, for example attribute lists, from previous studies or from published data. There is no harm borrowing, but not without giving some thought to the quality of the data that are being borrowed. Unduly, small sample sizes, poorly worded questions, imbalanced rating scales, and so on should be a cause for concern.
- Debugging a questionnaire, especially if computerized, for ensuring operational integrity.
- Pretesting a questionnaire to ensure comprehension and answerability is good research practice.
- If data are collected in multiple languages, not only should the translation be ratified, but the questionnaire should also be translated back in the language originally written to ensure minimum distortion of meaning and intent.
- Sample quality is a major issue, even when the sample is drawn from panels. MR proposals should address issues related to sample quality with as much specificity as possible. Results and insights provided by the study are only as good as the quality of the sample.
- If the research design calls for human interviewers, details concerning interviewer training and supervision should be presented. The goal of quality control procedures here is to minimize nonsampling error owing to interviewer bias.

- The discussion on quality control should also cover data cleaning and the treatment of missing data. The latter can be especially problematic as it results in unusable sample, and hence a waste of resources.

Neither sampling error nor nonsampling error can be entirely eliminated. But meticulous attention to detail and processes and diligent execution can minimize them.

PROJECT SCHEDULE

All activities from initial consultation with the client to the final deliverables should be presented in the project schedule. If contingencies need to be planned for, they should be

discussed separately. An example of a contingency is the need for factoring in the impact of a competitor's product launch on the client's product concepts being evaluated in the study. The data collection may have to be delayed if the competitor's product launch gets delayed. The project schedule for a quantitative study on migraine conducted with neurologists is provided in Figure 2.

PRODUCT AND SERVICE DELIVERABLES

A research project has both a product and a service component attached to it. An information product in the form of a report containing results and findings will be delivered to the client at the end of the study. However, service

| Project schedule | |
|--|-------------|
| Activities | Duration |
| Client discussion and finalization of project specifications | One week |
| Review of prior research | 3–5 days |
| Development of quantitative screener and questionnaire | One week |
| Client feedback and approval | One week |
| Programming and debugging questionnaire | One week |
| Pre-testing and finalization of questionnaire | 7–10 days |
| Data collection and tabulation | Three weeks |
| Data analysis and presentation development | 2–3 weeks |
| Presentation of results | Two hours |
| Strategy workshop | Four hours |

Figure 2 Project schedule.

is also provided during the course of a project in terms of briefings, keeping the client updated, providing early top line results, and so on. Complete details of both product and service deliverables likely to be provided to the client should be presented in this section.

It is easy to perceive this section to be a simple narrative listing of tables, reports, and other tangibles. What is often overlooked is that the sum of all deliverables, product and service, is the total value the client receives from the MR service provider. The amount that the client will have to pay for this value follows immediately in the next section. By definition, therefore, it should be in the best interests of the MR service provider to provide a complete picture of the price-value proposition represented by the proposal, without resorting, of course, to exaggeration and false claims.

RESEARCH INVESTMENT

There is a reason why the word investment is preferred to cost. A research project is an investment to augment the decision-making effectiveness of a company. The value of an MR project does not end with the mere act of data collection. Its value is likely to be felt and experienced for some longer period of time.

Before presenting the investment, it is advisable to list once again what the client is getting for their investment. A detailed activity-related break down of the total estimated investment should also be provided. For example, if the MR proposal recommends the development of a web-based simulator in response to an RFP for a conjoint choice-modeling study, the costs associated with the development of the simulator should be presented separately. The accepted practice is to break down the costs by geography, by subpopulation, and by the different value-added activities (data collection, tabulation and analysis, modeling, and so on.) If the MR service provider is willing to provide certain benefits without charging for them, specific mention should be made of it; of both the benefit to be delivered and that there is no charge associated with the delivery. For example, the last activity in the project schedule presented in Figure 2 is a Strategy Workshop. The MR company may be willing to offer this service at no

extra charge to the client. This is not uncommon. MR service providers often offer additional value in the interests of building lasting relationships, or to boost their chances of winning the contract.

PROJECT EXECUTION TEAM – WHY US?

As discussed earlier in the article, an MR proposal is both an *information* document and a *sales* document. MR service providers submit proposals because they want to win the contract. Additionally, as discussed in the *Deliverables* section, the client derives both *product* and *service* benefits from an MR project. The company submitting the proposal, its experience and pedigree, the project team supporting the client on the project are all part of the overall value offering.

The purpose of this section is to provide assurance and to sell. The client would like to be assured that their project will be designed and executed by competent, easy to work with professionals and that the overall experience will be enriching and hassle free. The service provider submitting the proposal would like to be rewarded with the project – partly because of the resources spent in developing the proposal and partly because the service provider may genuinely believe it deserves the contract. The project team, the names and faces, of its members and their brief professional biographies provide the assurance. The service provider's credentials, qualifications, its track record, and its experience provide the basis for selling the proposal.

CONCLUSION

Companies like P&G, Citi, Tesco, and Coke regularly conduct MR projects to provide relevant and timely market information to their decision makers. MR service providers bid for this business by responding to RFPs and submitting proposals. The MR proposal offers competing service providers the opportunity to show case their knowledge and their experience in bidding for the business. In today's complex and uncertain environments, systematic approaches that demonstrate rigorous thinking and skillful application of subject matter expertise to the client's business problem are likely to enjoy a higher

14 marketing research proposal

probability of success. It is for this reason that the framework presented in this article emphasizes structure, sequence, and rigor in the development of the MR proposal.

research reliability and validity

Rex Yuxing Du

Before we discuss research reliability and validity, it is useful to understand the *true score model*, which provides a framework for understanding the accuracy of any research instrument (Malhotra, 2006). According to the *true score model* $X_O = X_T + X_S + X_R$, where X_T denotes the underlying phenomenon the researcher sets out to investigate, X_O the actual observation made by the researcher regarding X_T . Any discrepancy between the two can be characterized as an error or inaccuracy. The discrepancy between X_T (the truth) and X_O (the observation) can be further divided into X_S (systematic error) and X_R (random error). Systematic error affects the accuracy of a research instrument in a constant way. The impact of random error, on the other hand, is not constant because it is caused by transient factors that affect the research instrument in a haphazard, unpredictable way.

According to the *true score model*, perfect reliability is achieved when $X_R = 0$ (i.e., there is no random error), and perfect validity is achieved when $X_T = X_O$, and $X_S = X_R = 0$ (i.e., there is neither random nor systematic error). In other words, perfect validity implies perfect reliability. It is important to note that, while unreliability implies invalidity, reliability does not in itself imply validity. Put differently, reliability is a necessary, but not sufficient, condition for validity.

Achieving perfect validity, or even merely perfect reliability, is desirable. Unfortunately, in practice, it is impossible to eliminate all possible errors, be it systematic or random. What researchers can do is to devise various methods to assess the nature and extent of these errors, and, if feasible, come up with remedies to minimize them. The rest of the article focuses on the most commonly used approaches in assessing research reliability and validity, especially in the context of measurement (also see VALIDITY AND RELIABILITY; Malhotra, 2006, pp. 283–287; Aaker, Kumar, and Day, 2006, pp. 302–304). VALIDITY IN EXPERIMENTATION addresses validity in the context of experimentation.

A *reliable* research instrument should demonstrate consistency, that is, leading to the same observation/conclusion each time it is used with the same subjects under the same condition. Assessing reliability is essentially about gauging the size of the random error. There are several basic operational approaches to do so, including internal consistency, parallel forms, test–retest, and interrater, all of which involve some sort of repetition, because random errors by definition should not reoccur in the same way when the research instrument is applied repeatedly.

Internal-consistency reliability is probably the most frequently used measure of reliability. It refers to how well the multiple items that are designed to capture the same underlying construct yield similar results, which can be estimated in several ways, including average interitem correlation, average item–total correlation, split-half, and Cronbach's alpha.

Average interitem correlation can be derived by first calculating the correlation between each pair of items and then taking the average of all these correlations. For example, for an instrument with six items, one will have 15 different item pairings (and therefore, 15 interitem correlations). A slight variation of average interitem correlation is *average item–total correlation*, which also uses the interitem correlations. The only difference is that, in calculating average item–total correlation, one needs to compute the sum of all the items of the original instrument and use that total as an additional item when calculating the average correlation between the items. The higher the average interitem or item–total correlation, the higher the internal-consistency reliability.

To calculate *split-half reliability*, one randomly divides all items that are intended to measure the same construct into two sets. The entire instrument (i.e., all items from both sets) is administered to a sample of subjects and the total score for each set is then calculated. The split-half reliability is simply the correlation between these two total scores.

Cronbach's alpha (or *alpha coefficient*) is probably the most frequently used estimate of internal consistency and is closely related to split-half reliability. Imagine that one computes one split-half reliability and then randomly divides the items into another two halves and

2 research reliability and validity

recalculates, and keeps doing this until all possible split-half reliability estimates have been calculated. Cronbach's alpha is mathematically equivalent to the average of all possible split-half reliability estimates; of course, in practice, statistical software packages have more efficient algorithms for calculating it.

To assess *parallel-forms reliability* (or *alternative-forms reliability*), one needs to create two alternative forms. One way to accomplish this is to create a large set of items that address the same construct and then randomly divide them into two sets. Both sets of items are administered to the same sample of subjects. The correlation between the two alternative forms can then be used as an estimate of reliability. One major challenge of this approach is that one has to generate a large number of items that reflect the same underlying construct, which is often not easy in practice. Furthermore, this approach makes the assumption that the randomly divided two sets are parallel or equivalent. Even by chance this sometimes will not be the case.

Parallel-forms reliability is often confused with split-half reliability. With split-half reliability, one intends to have an instrument that is used as a single measurement and only creates random split-halves for the purpose of estimating reliability. By contrast, the parallel-forms approach is typically used in situations where one intends to have two forms that can be used independent of each other and are functionally equivalent, as alternate measures of the same construct. As compared to all the other internal-consistency approaches, the parallel-forms approach shares a major constraint—the researcher must have multiple items designed to measure the same construct.

Test-retest reliability does not require multiple items and can be estimated by applying the same instrument to the same sample on two different occasions. The closer the correlation between the two separate measurements is to one, the more reliable the instrument. The underlying assumption of test-retest reliability is that there is no substantial change in the construct being measured between the two occasions, which is more likely to be true when the amount of time elapsed between the two measurements is short.

Consider the following example. A group of respondents are tested for IQ; each respondent

is tested twice, with the two tests being, say, one month apart. One can use the correlation coefficient between the two sets of IQ-scores to assess the test-retest reliability of the instrument. In the ideal case, the before-and-after scores coincide for each respondent, leading to a correlation of one. In reality, this is almost never the case—the scores produced by most respondents would most likely be different from one test to the other. A major limitation of test-retest reliability is the potential “practice effect,” that is, respondents “learn” to answer the questions after the first test, which can affect their responses to the same questions in the second test. For example, the IQ-scores may tend to be higher in the retest.

Interrater reliability (or *interobserver reliability*) is one of the best ways to estimate reliability when the research instrument requires observation or human judgment. It refers to the degree to which two raters are being consistent in their observations or judgments using the same instrument. Interrater reliability can be estimated in two ways, depending on whether the measurement is categorical or continuous. If the instrument consists of categories, one can calculate the percent of agreement between the raters. If the instrument is continuous, one can calculate the correlation between the ratings given by the two raters. One might use the interrater approach, especially when one is interested in using a team of raters and wants to make sure they yield consistent results. If one gets a suitably high interrater reliability, one can justify allowing them to work independently. By contrast, one might use the test-retest approach when one has only a single rater.

Each of the above approaches to assessing reliability may lead to different results. In general, the test-retest and interrater reliability estimates tend to be lower in value than the parallel-forms and internal consistency ones because the first two involve measuring at different times or with different raters.

Validity is about whether a research instrument really captures what it is supposed to examine. Major types of validity include face, content, criterion (concurrent and predictive), and construct (convergent, discriminant and nomological).

Face validity (or *consensus validity*) refers to the logical appropriateness of the instrument used.

For example, one might argue that whether a buyer recognizes an advertisement can be used as an indicator of past advertisement exposure. This is logically appropriate (or of face value), and the instrument would therefore appear to have face validity. Face validity is usually established through little more than common sense. (Of course, how well a person recognizes an advertisement might depend on how interested the person was in the advertisement or some factors other than past exposure.)

Content validity refers to the inclusion of all relevant aspects of the underlying construct. For example, a content valid measure of employee satisfaction should cover a full range of experiences and attitudes (e.g., salary, benefits, work-life balance, work hour, nature of work, mobility, bureaucracy, culture, career development opportunities, and so on) that are relevant to the construct of employee satisfaction. Common sense would indicate that a measure of employee satisfaction lacks content validity if it involves only salary and benefits.

In practice, developing a content valid instrument often requires a carefully selected and balanced sample of elements in order to represent the overall construct. This is because of the fact that many constructs are made up of prohibitively long lists of elements and it may be impossible to measure everything. Thus, a selected sample of elements that can represent the majority of all relevant elements is often used to ensure content validity. For example, in an academic examination, the instructor who sets the questions needs to measure whether his/her students have mastered his/her course (overall construct), but he/she cannot test his/her students' knowledge in everything that he/she has taught over the course of a semester – the examination would otherwise last for days! Fortunately, any reasonable instructor would craft an examination containing only a subset of all possible questions to assess his/her students' knowledge. Furthermore, an examination of content validity probably would include questions from each relevant chapter, systematically (but subjectively) selected by the instructor. Taken together, the selected questions should be representative of the course as a whole and do a good job in assessing a student's overall mastery of the course material.

Unfortunately, in marketing research applications, establishing content validity is not as straightforward as setting an examination. The researcher usually needs to first clearly define the construct that he/she intends to study. Then, the researcher needs to develop a comprehensive list of elements relevant to the measurement of the overall construct through a systematic search process (researcher experience, qualitative and secondary researches are often employed to generate the list). Finally, the researcher would select a "best" subset of elements that probably best represents the overall construct. Of course, the whole process is inherently subjective and therefore content validity can, at best, be approximated but not guaranteed.

Criterion validity is established on the basis of certain empirical criteria. In particular, an instrument is said to be of criterion validity if it varies in an expected and significant way with another or another set of variables. In general, there are two forms of criterion validity, concurrent and predictive, depending on the measurement time of the external variables.

Concurrent validity involves relating the measure of interest to external variable(s) taken from the same time period. For example, one may hypothesize that the overall satisfaction of a firm's employees should be tied to the firm's financial performance at the same time period. Concurrent validity would be established if one observes positive correlation between measurements, taken from the same time period, of employee satisfaction and firm financial performance.

Predictive validity refers to how well a measure of interest predicts certain characteristics or behaviors of some related entity *after* the measurement was taken. For example, the mathematics test scores of a class of third graders should be a good predictor of how well each student will perform in fourth grade mathematics. Another example is predictive genetic testing, which uses patients' genetic makeup to predict the likelihood of developing certain diseases. Note that this is distinct from regular medical checkups that test patients' conditions in order to determine if they are currently ill, which establishes the concurrent validity of the medical checkups. Finally, while having predictive validity established seems to

4 research reliability and validity

suggest that there is causal relationship between the measured construct and the criterion, it is not always true.

Construct validity refers to whether the researcher is, indeed, measuring the construct he/she sets out to measure. It is often possible for a researcher's instrument to capture a related construct that is actually different from the one that it was intended. For example, a teacher who intends to use an examination to measure his/her students' understanding of the course material may instead measure the students' ability to memorize and regurgitate.

Obviously, in order to establish construct validity the researcher must first have a deep understanding of the underlying construct. The researcher needs to be able to define the construct explicitly and show that the construct's conceptual definition logically connects to its operational definition. Construct validity is often considered the most difficult to assess because of the potential theoretical complexity and the unobservable nature of many of the constructs in marketing research. For example, is share of category requirements a good operational definition of brand loyalty, or is it confounded with some other factors such as needs for variety?

In practice, there are three types of construct validity that are often assessed: convergent, discriminant, and nomological. Establishing all three types of construct validity is difficult and often requires the accumulation of findings from multiple studies measuring similar constructs using similar instruments.

Convergent validity refers to whether a measure follows the same pattern as other measures of the same underlying construct. When a construct is one-dimensional, various measures that are supposed to represent it

should be highly correlated with each other. Otherwise, either the measures are poor (invalid) or the construct is multidimensional.

Discriminant validity is the reverse of convergent validity and refers to whether a measure follows a different pattern than other measures that are supposedly *not* reflecting the same underlying construct. A measure of discriminant validity should exhibit low correlation with other measures of constructs that are theoretically unrelated to the construct of interest.

Nomological validity refers to the degree to which a construct behaves as it should within a nomological set (i.e., a collection of constructs that theoretically relate to one another, often represented in a diagrammatic format). Nomological validity is established when the measure of the key construct behaves in the way prescribed by the nomological set.

An excellent metaphor for the *relationship between reliability and validity* is that of shooting a target with a rifle. The center of the target could be thought of as the construct that is being measured. For each subject, taking a measure is like taking a shot at the target. If the instrument (i.e., the rifle) is perfect, one would hit the center of the target every time a subject is measured. Otherwise, one would miss the center.

Figure 1 shows four possible scenarios. The first one, where all the hits missed the center of the target and landed in a small area at the top-right corner, represents an instrument that is reliable but not valid (that is, it is consistent but wrong). Put differently, the instrument is consistently measuring something that is systematically different from the construct that it has been designed to measure. The second, where hits were spread randomly across the target in

Figure 1 Comparing reliability and validity.

all directions, rarely landing at the center, represents an instrument that is not reliable but may be valid at the aggregate level. In other words, although the instrument gets an erroneous answer from most subjects (i.e., not reflecting the true value of the underlying construct), the errors are not systematically off the center of the target; when aggregated across the sample, the errors balance each other out and as a result, one may get the right (valid) answer for the sample as a whole. That said, the instrument is not valid at the individual level. The third scenario shows a case where the hits were spread across the top half

of the target, all missing the center. In this case, the measure is neither reliable nor valid. The last shows a scenario where all the hits landed at the center of the target (or very close to it), representing a measure that is both reliable and valid.

focus groups and depth interviews

Dennis W. Rook

As long as there have been marketplaces, business people have gathered intelligence about them, in both formal and less structured ways. For centuries, marketplace information has been provided by explorers, scouts, runners, agents, representatives, salesmen, spies, tax gatherers, census takers, and other government functionaries with vital statistics (Levy, 1994). The twentieth century witnessed the steady proliferation of companies, information gathering technologies, and generalized procedures that collectively comprise today's global multibillion-dollar market research industry. Management's ongoing need to obtain information from consumers plays a central role in marketing analysis, strategy, planning, and control. Historically, marketers gathered such data through extensive surveying or polling that generated statistical measures of consumers' demographic characteristics, product and media consumption behavior, purchase intentions, and so on.

This type of information assists managers' strategic and tactical decision making in numerous ways. However, the explanatory power of survey data is limited by its largely descriptive, factual, and somewhat mechanical qualities. The subtler factors that explain why, for example, women like Brand X significantly more than men often lie below the surface and are likely to elude blunt survey instruments with their direct questions, fixed-format responses, and few degrees of freedom. When grumbling about survey research was gaining momentum in the 1930s, psychological theories, insights and methods had begun to filter into marketing thought and quickly expanded and enriched marketing's intellectual and substantive domain. A watershed in this period was an article by the renowned psychologist Paul Lazarsfeld (1935): "The Art of Asking Why in Marketing Research." Some scholars view this article as the seminal force in opening the door to behavioral science thinking and methods in marketing research (Levy, 1994). No longer wedded so strongly to quantitative survey methodology, various types of what came to be known as

qualitative research emerged onto the marketing scene.

Within the qualitative research arena (*see* EXPLORATORY RESEARCH; MOTIVATION RESEARCH; OBSERVATION METHODS), individual marketing researchers designed their studies around talking with and interviewing consumers either on an individual basis or in group discussions. Today various technologies facilitate the collection of information about consumers' shopping activities (scanner data, *see* ELECTRONIC SCANNER SERVICES) and media consumption (Nielsen data, *see* PURCHASE, SCANNER, AND MEDIA PANELS) electronically and almost invisibly, with minimal consumer involvement. These technological advances, however, hardly eliminate marketers' needs to talk with consumers live and in person. One-on-one interviews are most commonly called *individual depth interviews (IDIs)*, and group discussions are described as focus groups. Although, they share common origins, IDIs and focus groups are quite different in significant ways and have various strengths and weaknesses.

INDIVIDUAL DEPTH INTERVIEWS

The following material presents a brief history of IDIs and identifies their distinctive qualities and uses. Then the discussion considers the principles that guide the design, structure and gathering of data from individual consumers and other marketplace intermediaries such as purchasing agents, wholesale and retail personnel, and others.

Origins and evolution. IDIs migrated into the marketing-research toolkit from the fields of clinical psychology, qualitative sociology, and cultural anthropology. Arguably the single strongest influence came initially from clinical psychology, whose nondirective individual interviewing and imaginative projective techniques were easily and successfully adapted for commercial purposes. In the early days, roughly from 1935 to 1960, market research uses of IDIs were frequently guided by Freudian and neo-Freudian thought. Perhaps more than any psychologist ever, Sigmund Freud's compelling and provocative theories achieved

2 focus groups and depth interviews

deep penetration into the popular culture during this period, and filtered down into cocktail party chatter about the symbolic meaning of cigars and convertibles, among other things. These developments represent an historic intellectual and managerial shift from an emphasis on counting and measuring things toward the then exciting and uncharted research territory involving consumers' motivations and meaning systems. In fact, most scholars refer to this period as the "Motivation Research" era (*see MODELS FOR CATEGORICAL DEPENDENT VARIABLES*). In the 1950s, a flurry of academic articles, trade publications and books discussed the concepts, tools, and findings of motivation research, which overwhelmingly relied on IDIs (Martineau, 1957; Newman, 1957; Smith, 1954).

Depth interviews' nature and uses. The primary purpose of a depth interview is to achieve understanding that goes beyond the obvious and surface-level to reveal consumers' basic values, predispositions, needs, feelings, and motivations. For example, when a consumer is asked to explain his reasons for purchasing his current car, a frequently obtained initial response is: "I liked its look and I got a good deal on the price." This rationalized explanation actually provides very little information, as few consumers would be likely to report wanting to buy ugly and overpriced cars. Additional probing might, hypothetically, yield the finding that this particular 46-year-old male consumer purchased a convertible sports car to signal his financial success and sexual availability. Clearly, even the most self-aware consumer is unlikely to offer such an intimate explanation initially, so it must be teased out during a lengthy interview process that relies on both direct and more subtle approaches to the question(s).

Probably the most renowned among the early migrants from clinical psychology to marketing research was Paul Lazarsfeld's student Ernest Dichter, who fled Nazi Europe in the 1930s and set up business in New York, not as a clinical therapist but as a corporate consultant. He achieved early success and enjoyed a long consulting career with America's top businesses, and his company also provided a training ground for young qualitative researchers, many of whom

went on to have their own successful, independent careers.

A signature of Dichter's research was its analytic reliance on the most basic human dialectics that cut across issues and tensions involving aspects of gender, social status, age, and (especially) sexuality, along with the attendant interpretation of symbolic meanings that swirl around consumption, products, and brands. Anchoring market research in such "deep" topics and concerns is one identifying aspect of IDIs. Dichter's numerous studies collectively provide a prototype of what "depth" research is. His findings and interpretations were almost always fresh, original, and thought provoking; sometimes they were quite sensational and controversial, and filtered into the media and public discourse. His *Handbook of Consumer Motivations* (Dichter, 1964) is a fascinating compilation of many dozens of studies across the marketplace landscape. Excerpts from two client studies are included to illustrate his analytic approach:

Study 1: Baking does not play the same role in the life of the modern woman that it did even as recently as one or two generations ago . . . The modern woman no longer has to bake of necessity . . . however, she continues to take an interest in baking because of the emotional satisfactions which she derives from this activity. Baking is an expression of femininity (that) evokes pleasant, nostalgic memories . . . (and) provides a feeling of love and security . . . The most fertile moment occurs when the woman pulls the finished cake, bread loaf, or other baked product out of the oven. In a sense it is like giving birth. How did it turn out? Did it fulfill expectations? (p. 21)

Study 2: There is probably a major difference between . . . men who use electric shavers and those who use razor blades (that) is anchored in the basic psychological significance of shaving. Each time a man shaves he is, on the one hand, robbing himself of a masculinity symbol, on the other hand reasserting it . . . The shaver who uses razor blades is a person who enjoys the ritual that goes with it . . . Razor blade users who have tried electric shavers often rationalize that they do not get a close enough shave. While this may be true, it is also very likely that a deeper reason for not favoring a dry shave is that it eliminates much of the elaborate and somewhat masochistic ritual of wet shaving. (p. 184)

Some people might find the comparison of baking to giving birth utterly preposterous, yet the Pillsbury Company seemed to appreciate the connection, and for many years their advertising reminded American housewives that “Nothin’ says lovin’ like somethin’ from the oven, and Pillsbury says it best.” Similarly, Gillette seems well aware of men’s ambivalence about the ritual of shaving. Their long-term sponsorship in the 1950s and 1960s of TV’s Friday Night Fights positions their razors in an ultramasculine venue, while their more recent slogan, “Gillette: the Best a Man Can Get,” appeals to contemporary metrosexual consumer interests and motivations.

TECHNIQUE: STRUCTURE AND PROCEDURES

Several distinctive structural and procedural qualities of an IDI facilitate achieving the enhanced level of understanding that the technique’s pioneers intended. One of the central elements of depth interviews is simply assumed and rarely discussed: the *one-on-one* nature of the questions and conversations. Individuals today rarely receive the undivided attention of another for any significant length of time except when they pay for it in the professional services domain. This feature makes depth interviews experientially unique and tends to induce feelings of intimacy and privacy, which further encourages greater self-disclosure than one would obtain in either survey or focus-group research. Depth interviews are also generally *lengthy*, lasting between 1 and 2 hours, a characteristic embedded in the title of Grant McCracken’s delightful book, *The Long Interview* (McCracken, 1988). Surveys and even focus groups often seem like interrogations rather than interviews, with rapid-fire direct questions posed to consumers about a myriad of topics, with the expectation that responses will be made quickly and without much elaboration. Depth interviews are, or at least should be, in much less of a hurry to extract unambiguous answers to specific questions.

Another characteristic of depth interviews is their reliance on *open-ended questions* that offer greater degrees of response freedom, which encourages more thinking and reflection on the consumer’s part. For example, asking bluntly “Do you like Nike?” would tend to elicit a

simple yes or no response, and require additional probing about the underlying reasoning. A depth interview would open up and broaden, essentially, the same question by asking, “Tell me how you feel about Nike.” Open-ended questions not only capture a broader range of responses, but they also make for interviews that are more *conversational* in nature. This does not, however, imply that the dialogue is the same as that between friends and family, with the two parties going back and forth. Reflecting their clinical psychological origins, the depth interviewer asks a question and lets the respondent run with it without much intervention, often merely nodding or making brief verbal comments to encourage continued explanation beyond the initial response. When an individual seems to have exhausted the topic, veered off into tangential territory, or simply run out of steam, the interviewer moves on to the next topic or question.

Being conversational in nature does not imply that depth interviews are without clear and purposeful structure. Like focus groups, they tend to *flow from general to increasingly specific* questions. To illustrate, in a research project sponsored by a soy sauce manufacturer some years ago the interview discussion guide was designed to cover eight increasingly narrow thematic topics, with several questions under each. The interview began with three questions about the respondents’ (1) overall lifestyles and four questions about (2) their cooking and meal preparation patterns and activities. This was followed with four questions about (3) “ethnic” food trial and likes, three questions about (4) “Oriental” food, and then nine questions about consumers’ (5) understanding of, first experiences with, and current uses of soy sauce. Then four questions probed their (6) perceptions of different soy sauce brands. The interview concluded with the collection of consumers’ (7) evaluations of concepts statements for new soy sauce products and of (8) different advertising storyboards. A condensed sample of the discussion guide is included in the Table 1. Despite the study’s obvious commercial purposes, the nature and flow of the topics and questions provide the basis for a relatively naturalistic consumer conversation. Although, some managers will likely obsess

Table 1 Soy sauce depth interview discussion guide.

Overall Lifestyle

1. First, please tell me a bit about yourself . . . your work . . . family.
2. What are your special interests . . . leisure activities?
3. How do you think your lifestyle is different from your friends?

Cooking and Meal Preparation

4. Do you like to cook . . . compared to your friends and relatives?
5. What kinds of dishes do you make on a regular basis . . . why these?
6. What kinds of dishes do you make for special occasions?
7. What kinds of meals do you enjoy cooking the most . . . why?

Ethnic Food

8. What kinds of ethnic food you especially like . . . what is its appeal?
9. In your own cooking, do you experiment with ethnic or foreign foods?
10. Tell me about some ethnic dishes you have made recently. How did they turn out?
11. Have your tastes changed in the kinds of ethnic foods you like . . . why?

Oriental Food

12. What are your feelings about Oriental food . . . likes . . . dislikes?
13. What are your favorite Oriental dishes . . . least favorite?
14. Are you making more or fewer Oriental dishes than you used to . . . why?

Soy Sauce: Basic Understanding and First Experience

15. You said you use soy sauce. Where does it come from . . . where is it used?
16. Soy sauce is made in China, Japan and the United States. Does it matter to you where it comes from?
17. What was your first experience with soy sauce . . . where . . . when? How did you like it?

Soy Sauce: Purchase and Usage

18. How often do you buy soy sauce? Is it a planned or impulse purchase?
19. Tell me about the dishes you make that have soy sauce as an ingredient.
20. Is soy sauce more a part of your everyday cooking or is it more for special occasion meals?
21. What are some non-Oriental dishes in which you put soy sauce?
22. Do you use soy sauce more or less often than you used to . . . why?
23. Do you also use soy sauce as a condiment on the dining table?

Soy Sauce: Brands

24. What soy sauce brand do you usually use . . . why? What makes it better than other brands?
25. What other brands of soy sauce are you aware of? What do you like or dislike about each of these?
26. If the store was out of your favorite brand, what would you buy instead?
27. Here is a picture of two women grocery shopping. One woman prefers La Choy soy sauce and the other prefers Kikkoman. Tell me a story about what each one says about her favorite brand . . . and what are the two women like?

Soy Sauce: Product Concepts and Advertising Evaluations

28. New soy sauce product concept evaluations (not available)
 29. Advertising copy testing
-

about the product concept and advertising “test” results (questions 28 and 29), more enlightened ones will appreciate and use the experiential depth that lies behind consumers’ evaluative responses.

Although they depend heavily on open-ended questions, depth interviews also rely frequently

on the unique data elicitation qualities of *projective methods* to tease out answers to questions that more direct approaches often fail to provide (see PROJECTIVE TECHNIQUES). Projective methods, also with clinical psychological origins, are a diverse family of techniques (story telling, sentence completion, picture drawing, word

association, dream exercises, symbol matching, among others) that are particularly useful in situations in which consumers for various reasons are likely to be unable or unwilling to articulate the information that researchers need (Rook, 2006). Question 27 in the Table 1 is an abbreviated example of the thematic story telling technique. The creative, constructive, and indirect nature of projective techniques, along with their high degrees of response freedom, permit access to deeper levels of the human psyche where consumers' emotions, visual imagery, impulses, fantasy, and conflicts reside. Finally, depth interviews generate a *large amount of narrative and other expressive data* compared to most market research protocols. The large amount of data offers rich perspectives for interpreting consumers' stories and their underlying meanings. When sample sizes are large the amount of data can seem overwhelming, so researchers have developed software programs (NUD*IST, Ethnograph) for coding and sorting responses, although it is not yet clear that applying quantitative content analytic tools to qualitative data is particularly appropriate or incrementally productive. For a broader discussion of the analysis of qualitative data.

FOCUS GROUPS

Although, Ernest Dichter preferred individual over group interviews, his consulting company trained a large number of the first generation of focus-group researchers. Many other influential scholars and practitioners were involved, whose involvement in the evolution of focus-group interviewing is covered below. Following this, the discussion considers the nature and uses of focus-group research as well as the main procedural details (*see also* EXPLORATORY RESEARCH).

Origins and evolution. Originally called "*focused*" interviews (Merton and Kendall, 1946), this technique came into vogue after World War II and has been a part of the social scientist's tool kit ever since. Researchers in numerous behavioral science disciplines have relied on focus groups as a source of primary data. The fields that have embraced, at various points in time, research with groups include

education, sociology, communications, the health sciences, organization behavior, program evaluation, psychotherapy, social psychology, gerontology, political science, policy research, and marketing. At the beginning, the theoretical underpinnings of focus groups emerged from what pioneer Alfred Goldman describes as a "rich stew of sociopsychological and psychotherapeutic traditions and techniques" (Goldman and McDonald, 1987, p. 3).

The successful uses of focus groups in evaluating World War II morale and training films did not go unnoticed by the marketing-research community. The procedures developed by Lazarsfeld and Merton were imported directly into CBS' research of pilot radio and television programs, and are still used today. Although, it is likely that some innovative business studies used focus groups as early as the 1930s, their popularity grew dramatically from the 1950s onward (Leonhard, 1967; Smith, 1954). Marketing researchers quickly discovered the versatility of the focus groups in addressing numerous concerns related to designing products and services; obtaining consumers' perceptions of prices, brands, and retail environments; and their reactions to advertising and other marketing stimuli. Also, there is some speculation that, in the days before the rise of commercial interviewing facilities, interviewers grew weary of lugging around heavy reel-to-reel tape recorders for capturing their in-home conversations with consumers, and responded positively to the idea of sitting down to interview a group of housewives in someone's family room.

In comparison to statistical research, focus groups are more user friendly, and can be fielded and analyzed relatively quickly. They also provide an office get-away that is often social and entertaining, as well as insightful. Just like IDIs, the emergence of focus-group theory and practice is linked to the motivation research era of the 1950s (Smith, 1954), also with a strong intellectual grounding in Freudian and neo-Freudian thought. Groups conducted in this tradition tend to share the exploratory, interactive, playful, and confrontational qualities of clinical psychological groups. By contrast, focus groups rooted in social psychological thinking tend to be more evaluative in purpose, direct

6 focus groups and depth interviews

in questioning, and lower in respondent interaction. Such focus groups are often heavily involved in gathering consumers' reactions to product concepts, marketing communications, and competitive brands.

The use of focus groups expanded steadily since they were first introduced, and the pace increased over the past quarter century. Perhaps the most compelling quality of focus groups is their delivery of live flesh and blood consumers for observation by marketing managers who are typically hidden behind a one-way mirror, unseen by the participants. This sharply differentiates focus groups from IDIs, which managers typically have little interest in viewing, since this would be far more time consuming and lacking in the entertainment value of group discussions and interactions. Today focus groups account for as much as 80% of the \$1.1 billion spent domestically on all varieties of qualitative research (author's estimate). Equally significant, focus groups' share of mind is extremely high, as many managers virtually equate "focus groups" with "qualitative research," having little awareness of other qualitative techniques.

Focus-group nature and uses. A focus group involves a group discussion of a topic that is the "focus" of the conversation. The contemporary focus-group interview generally involves 8–12 individuals who discuss a particular topic under the direction of a professional moderator, who promotes interaction and assures that the discussion remains on the topic of interest. A typical focus-group session will last from 1½ to 2½ hours. The most common purpose of a focus-group interview is to stimulate an in-depth exploration of a topic about which relatively little is known. Focus-group research is uniquely suited for quickly identifying qualitative similarities and differences among people. Focus groups also provide an efficient means for determining the natural everyday language people use when thinking and talking about specific issues and objects, and for suggesting a range of hypotheses about the topic of interest. Focus groups may be useful at virtually any point in a research program, but they are particularly useful for exploratory research of uncharted territory (*see* EXPLORATORY RESEARCH). As a result, focus groups tend to be used early in research projects,

and are often followed by other types of research that provide more quantifiable data from larger respondent samples.

Focus groups have also been proven useful following analyses of large-scale, quantitative surveys. In these instances, focus-group research facilitates more nuanced interpretations of quantitative results and adds depth to the responses obtained in the more structured survey. Focus groups also have a place as a confirmatory method that may be used for testing hypotheses. This application may arise when the researcher has strong reasons to believe a hypothesis is correct, and where disconfirmation by even a small group would tend to result in rejection of the hypothesis.

Focus groups can produce quantitative data, but this is at odds with their nature and primary purpose, which is the collection and analysis of qualitative data. Like IDIs, focus groups, when properly designed and conducted, generate a rich body of data expressed in the respondents' own words. In focus groups participants can qualify their responses or identify important contingencies associated with their answers. Thus, responses have a certain ecological validity not found in traditional survey research. On the other hand, the data provided by focus groups may be idiosyncratic and unique to the group.

Although, focus groups can be conducted in a variety of sites, ranging from homes to offices, they are typically held in commercial facilities designed especially for focus group interviewing. Such facilities provide one-way mirrors and viewing rooms where observers may unobtrusively observe an interview in progress. Focus-group facilities may also include equipment for audio- or videotaping interviews and perhaps even small receivers for moderators to wear in their ears, so that observers may speak to them and thus provide input into interviews. In an age of on-line communication and video-conferencing focus-group facilities also tend to be equipped for "virtual" groups where the members may be broadly dispersed geographically and communicate through electronic media. Focus-group facilities tend to be situated either in locations that are easy to get to, such as just off a major commuter traffic artery, or in places like shopping malls, where people tend naturally to gather.

Technique: structure and procedures. The first characteristic is that of *focus*, which was first introduced by pioneers Merton and Kendall (1946). They explain that the basic purpose of the “focussed” interview (their preferred spelling) was to gather qualitative data from individuals who have experienced some “particular concrete situation,” which serves as the focus of the interview (p. 541). Alfred Goldman is prominent among the second generation of researchers who transitioned from clinical to marketing research uses of focus groups, and his article, “The Group Depth Interview” (Goldman, 1962) is widely considered a definitive classic that identifies three additional theoretical pillars of focus-group research. A second signature element is the objective to better understand the *group dynamics* that affect individuals’ perceptions, information processing, and decision making about the focal research topic. This is the main logic for conducting the research in a group rather than an individual setting, to allow observations of how and why individuals accept or reject others’ ideas. Also, stimulating interactions among group participants are hypothesized to generate more information than individual interviews would provide, although there is little empirical support for this position.

A theoretical quality they share with IDIs both in purpose and name is the elicitation of *in-depth data*. A main thread that connects the diverse family of today’s focus-group users and providers is a belief that live encounters with groups of people will yield incremental answers to questions that go beyond the level of surface explanation. Clinical psychology is rich with qualitative research tools and techniques such as projective methods and group involvement techniques that elicit the emotions, associations, and motivations that influence particular behaviors. Focus groups in the health sciences often address emotional, even life-and-death issues. Market researchers have similar, although generally less serious concerns about identifying the underlying behavioral factors that account for consumers’ attitudes, preferences, and motivations.

The history of focus-group theory and practice is part of the larger history of qualitative

research in the behavioral sciences. In comparison to most quantitative survey research, qualitative research is a contact sport, requiring some degree of immersion into individuals’ lives. This and its emphasis on meaning rather than measurement have contributed to its characterization as *humanistic* research. This is not meant to ennoble qualitative research; rather it simply points to a general orientation that includes empathy, openness, active listening, observations, and various types of interactions with research participants, which is markedly and experientially different from the prophylactic rating scales that survey researchers deploy.

Focus groups in marketing today tend to perform less well on the humanistic criterion. This is partly because of the tendency to field research more for evaluative than developmental or exploratory purposes, reflecting marketers’ voracious appetites for obtaining consumers’ critical reactions to new product concepts, advertising copy, and competitive brands. This is understandable and necessary, but such interests might – ironically – be better served through survey research rather than focus-group studies. Also, groups that are dedicated to evaluative polling tend to exhibit characteristics of a business meeting in which moderators misguidedly seek to achieve group consensus. Another factor that is likely to diminish a group’s humanistic qualities is the erroneous, but widespread belief that the moderator should ask every question that appears in the discussion guide, which often “destroys the elements of freedom and variability within the interview” (McCracken, 1988, p. 25).

In their early days in marketing research, the prototypic focus group was characterized by a relatively small number of loosely structured questions that center around a focal topic or stimulus, and encourage extensive discussion and probing. Structurally, focus groups and IDIs were quite similar. Overtime, focus groups have drifted away from their original emphasis on achieving in-depth consumer insights. Robert Merton’s own impression of focus groups in marketing concludes that they are “being mercilessly misused” (Merton, 1987, p. 557). Two factors have contributed to the decline in focus-group depth. First, focus-group discussion guides tend to include too many questions, which often makes the

experience more like a within-group survey than an interactive discussion. Rook (2003) quantifies the interaction between the number of questions in the discussion guide and the focus-group length. It is common today to have 30 or more questions, which can reduce the response time per respondent to 13 seconds or less. In these circumstances, the moderator is likely to feel hurried and unable to probe interesting or unclear responses, all of which militate against achieving in-depth information.

A second problem emerges from the tendency to use exclusively direct questions and verbal responses to them. This is not only inconsistent with the historical nature of focus groups it also defies current neuroscientific understandings about the workings of the human mind. These findings conclude that the vast majority of human thought is visual, metaphorical, and emotional, and resides deeply in neurological substrata. Access to these mental zones typically requires more subtle, indirect approaches to asking questions; and it suggests using nonverbal techniques that involve visualizations or role playing. Marketing professionals increasingly recognize the problem and the criticism of the focus-group research been growing for a decade. Some companies (Yahoo, America Online) have abandoned them almost entirely in favor of alternatives such as ethnography, which facilitates greater immersion into consumers' lives (*see* ETHNOGRAPHIC RESEARCH). The controversy peaked recently when best selling author Malcom Gladwell, in his 2005 keynote address at the American Association of Advertising Agencies' summer conference recommended that focus-groups research should be entirely abandoned. This caused quite a stir, since advertisement agencies are extremely heavy users of focus groups. The ebb and flow of focus-group research across and within various disciplinary fields, and the attendant intellectual elements of thesis, antithesis, and synthesis make focus groups an interesting and dynamic arena that continues to merit further consideration.

One problem that might not seem apparent in the literature, but looms large in the field is what Grant McCracken observes as an intellectual climate that reflects "substantially more concern with practice than theory" (McCracken, 1988, p. 15). This is particularly the case in marketing

research, where dozens of articles and books tend to emphasize the dos-and-don'ts surrounding the myriad of executional details involving recruiting participants, preparing discussion guides, selecting moderators, blocking time slots, inviting observers, ordering food, data analysis, and report preparation. As Rook (2003) suggests, the stage management aspects of focus groups often preoccupy researchers to the point where more basic issues are barely considered. In practice, researchers rarely step back to ask why they want to conduct research with groups rather than individuals, and why in a mirrored room instead of a natural setting? Greater consideration of these critical research design questions might invigorate the intellectual environment and reduce the perceptions of focus groups as research junk food.

CONCLUSION

Over 60 years ago, what we today call IDIs migrated into the marketing field and were quickly added to the marketing-research toolkit. The rapidity of their adoption was influenced by their intellectual partnership with the field of motivation research and its own growing popularity that was fueled by a steady stream of original, analytic insights that marketing managers found useful and actionable. IDIs were also promoted by the extraordinary larger than life research pioneers who sold them to innovative and courageous clients, and published their work in both trade and scholarly journals, including the *Journal of Marketing* and *Harvard Business Review*. Eventually, the neo-Freudian thinking that motivated much individual depth interviewing came under attack from scholars who argued in favor of cognitive and social psychological approaches and condemned the "excesses" of psychodynamic interpretations.

By the 1970s, focus-group research began to take off rapidly as IDIs ebbed. Focus groups had many selling points; the efficiency of a 2- to 4-hour data collection, the quick research turn-around this permits, the user-friendliness of the verbatim data, the voyeuristic aspects of watching people behind a mirror, the ecological validity of listening to live consumers, the entertainment value focus groups commonly provide, and the highly social nature of the event. These

factors and others contributed not merely to the popularity of focus-group research, but to the emergence of a focus-group industry comprised of over 1500 brick-and-mortar facilities for conducting the groups and many thousands of professionals who work in focus-group recruitment, recording and servicing (e.g., food and beverage; transportation, and hospitality). Compared to IDIs much focus-group research today is far afield from its theoretical and methodological roots, which may be inevitable with such mass appeal and usage. The criticism has been growing but it has also been helpful in providing suggestions for improving the quality of the focus-group research by using it in the ways it was intended, and continuing to innovate different focus-group techniques, formats, and locations. The good news is that with the explosive growth of ethnographic research and the renewed interest in projective methods, the next generation of marketing-research professionals will have a far more diverse toolkit to address marketing's far flung concerns and questions.

itemized rating scales (Likert, semantic differential, and Stapel)

Gary J. Russell

INTRODUCTION

One of the key challenges in marketing research is developing effective measures to describe consumer decision making. Researchers are interested in variables such as perceptions of product attributes, the relative importance of attributes in making choices, and preferences for different products. Measuring variables of this sort enhances managerial understanding of perceived product substitutability and the positioning of products relative to consumer segments. By tracking changes in consumer variables over time, managers can gain a better understanding of the determinants of important strategic constructs such as product awareness, consideration sets, brand equity, and market structure.

From a theoretical perspective, consumer variables that measure psychological reactions to the marketing environment are known as *attitudes*. Briefly stated, an attitude is a “psychological tendency that is expressed by evaluating a particular entity with some degree of favor or disfavor” (Eagly and Chaiken, 1993). Attitude measurement is very challenging for the simple reason that attitudes are not directly observable. For example, a researcher could infer that advertising messages strengthen brand positioning by measuring how consumer perceptions of product substitutability change in response to a new advertising campaign. Generally, the only way that a researcher can gain an understanding of these perceptions is by asking a representative group of consumers a set of structured questions. The success of the research will obviously depend upon which questions are asked, how these questions are constructed, and how the answers are interpreted.

Although many types of questions are possible, the focus of this article is a type of question known as an *itemized rating scale*. The phrase *rating scale* refers to a question in which the consumer is asked to indicate the strength of his or her attitude with respect to some entity (such as a product). The word *itemized* refers to

the fact that the consumer is allowed only to pick one of K different responses. These responses are arranged on the questionnaire in a way that suggests an ordinal set of relationships. If we think of an attitude as a continuous variable, then an itemized rating scale is an attempt to divide the attitude continuum into K ordered intervals (each corresponding to one of the K possible responses of the rating scale). In response to a question, the consumer reports the interval in which his or her attitude lies.

We first discuss a typology of measurement that identifies the universe of possible questions in survey research. We then review different types of itemized rating scales, and discuss practical issues of scale construction and interpretation. We conclude with a brief overview of modern methods of scale analysis that infer a continuous measure of attitude from the rating scale responses.

LEVELS OF MEASUREMENT

Psychometricians have long known that not all data collection procedures yield information with the same statistical properties. Following Stevens (1946), four different levels of measurement can be defined: *nominal*, *ordinal*, *interval*, and *ratio*. All possible questions that might be posed on a questionnaire can be classified into one of these groups (Table 1).

Stevens (1946) defines measurement as the assignment of numbers to objects (*see PRIMARY SCALES OF MEASUREMENT*). The weakest of these assignment rules is a nominal scale. A scale with nominal properties simply classifies entities into groups. A common example is household identification numbers in a panel dataset. The numbers serve to distinguish households, but otherwise have no meaning. On a survey questionnaire, a multiple choice response (such as marital status or gender) is considered a nominal scale. From a statistical point of view, nominal scales are usually called *categorical variables*. Relationships among nominal scales can be explored using statistical procedures designed for contingency tables (Bishop, Fienberg, and Holland, 1977).

A stronger level of measurement is the ordinal scale. As suggested by the name, ordinal scales allow the researcher to rank order

2 itemized rating scales (Likert, semantic differential, and Stapel)

Table 1 Levels of measurement.

| <i>Type of Scale</i> | <i>Distinguishing Characteristic</i> | <i>Allowable Transformations</i> | <i>Allowable Statistical Analysis</i> |
|----------------------|--------------------------------------|----------------------------------|---|
| Nominal | Naming outcomes | Permutation of labels | Frequency distribution log-linear models contingency table statistics |
| Ordinal | Ordering outcomes | Monotonic | Percentiles ordinal regression nonparametric statistics |
| Interval | Comparison of differences | $Y = a + bX$, where $b > 0$ | Means and variances general linear model |
| Ratio | Comparison of ratios | $Y = bX$, where $b > 0$ | Coefficient of variation percentage changes |

The four levels of measurement are ordered from nominal (low) to ratio (high). Higher levels of measurement possess all the properties of lower levels of measurement.

entities with respect to some characteristic. For example, marketing research surveys often ask respondents to rank order N products in terms of preference, using the scheme of 1 (high) to N (low). From this information, we can always infer which of two products is preferred more. However, we cannot tell how much more. Differences and ratios on an ordinal scale have no meaning. Specialized analysis procedures, known as *nonparametric statistics*, have been developed to analyze relationships among ordinal variables. Because itemized rating scales have ordinal properties, nonparametric methods can be quite useful in applied work.

Interval level measurements allow the researcher to compare differences between two points, but do not allow ratio comparisons. For example, consider centigrade and Fahrenheit temperature measurements, both of which are regarded as interval scales. Both measure heat, and are related by the linear expression $C = (F - 32)[5/9]$. Note that, the definition of one degree is different across the two scales, and the freezing points of water are also different. This arbitrariness in fixing the unit and the zero point of an interval scale makes ratio comparisons meaningless. Virtually all common statistical procedures (such as regression analysis) assume that the dependent variable has all the properties of an interval scale.

The highest level of measurement is the ratio scale. By definition, a ratio scale must have a well-defined zero point. For example, the dollar sales figure for Tide detergent in a particular store over one month period is a ratio scale. When comparing year to year sales, it is meaningful to state the current sales are a certain percentage higher than sales a year ago. In marketing research, consumers are sometimes asked to allocate 100 points across N brands in proportion to preference. This type of question, called a *constant sum scale*, can be considered a ratio scale of brand preference.

Although these distinctions may seem technical, they are important in determining which statistical analyses are appropriate for itemized rating scales. As noted earlier, itemized rating scales clearly have ordinal properties. However, it is common practice in marketing research to analyze the scales as if they have interval scale properties. In fact, itemized rating scales are also called *summed rating scales* because researchers will often compute an attitude score for each consumer by summing over a number of rating scales.

This ordinal versus interval measurement controversy has never been completely resolved. Early researchers in attitude measurement assumed that itemized rating scales provide interval level measurement, and felt justified in

analyzing the scales using statistical tools such as factor analysis. More recent developments in the psychometric literature, in particular *latent variable models* (Skrondal and Rabe-Hesketh, 2004), provide evidence that itemized rating scales are best regarded as ordinal scales, and should be analyzed with specialized procedures. We return to this controversy later in this article.

ITEMIZED RATING SCALES

The discussion so far has suggested that itemized rating scales have at least ordinal properties. Over the years, researchers have developed numerous scales having this property. Here, we briefly discuss three major types of itemized rating scales: *Likert*, *semantic differential*, and *Stapel*. These scales, shown in Table 2, are among the most commonly used scales in marketing research.

Likert scales. Likert scales ask the consumer to indicate his or her relative degree of agreement with respect to declarative statements. For example, we could write the statement “Wal-Mart has great service” and ask consumers to respond on a 5-point scale, where 1 means “Strongly Disagree” and 5 means “Strongly Agree.” Likert scales are widely used because

they can be adapted to studies of product positioning, consumer lifestyle, brand preference, customer satisfaction, and attribute importance. Likert scales (and, indeed, all the scales in Table 2) are *noncomparative* attitude measures: the consumer rates one entity at a time (*see* NONCOMPARATIVE SCALING TECHNIQUE). If the researcher wishes to compare attitudes across entities, the consumer must be asked to rate the various entities separately.

An interesting application of the Likert scale is *quadrant analysis*. In this analysis, consumers are presented with two sets of Likert scales, each scale with *K* possible responses. The first set asks the consumer the relative importance of various product attributes in selecting the product (1 = Unimportant to *K* = Important). The second set asks the consumer whether he or she believes that their usual brand has these same attributes (1 = Strongly Disagree to *K* = Strongly Agree). The responses on the belief scales are then plotted against the corresponding response on the importance scales. Because a large sample of consumers is surveyed, it is conventional to use the percentage of consumers using the top two rating categories (called *top-box responses*) as the plotting point.

An example of quadrant analysis for detergent brands is shown in Figure 1. Note that detergent attribute beliefs are positively associated with

Table 2 Itemized rating scales.

| Type of Scale | Example of Scale | | | | |
|-----------------------|--|---------|---------|---------|--------------|
| Likert | Wal-Mart provides great customer service. | | | | |
| | 1 | 2 | 3 | 4 | 5 |
| Semantic Differential | Strongly disagree | | | | |
| | Please rate Wal-Mart on the following scale: | | | | |
| | Great service | I-----I | I-----I | I-----I | Poor service |
| Stapel | Please rate Wal-Mart on the following scale: | | | | |
| | +3 | | | | |
| | +2 | | | | |
| | +1 | | | | |
| | Service | | | | |
| | -1 | | | | |
| | -2 | | | | |
| | -3 | | | | |

4 itemized rating scales (Likert, semantic differential, and Stapel)

Figure 1 Quadrant analysis.

detergent attribute importance. This is owing to the fact that brand competition forces manufacturers to produce products with attributes desired by consumers. To create quadrants, each axis of the graph is split at some point—in this case, the 50% mark. The lower right quadrant (high importance, low belief) indicates attributes that manufacturers should target for new-product development. In this case, consumers indicate that they value the ability of detergents to remove dirt and stains, but find their current brands lacking on these attributes.

Several practical considerations are associated with Likert scales. One of the first decisions is determining *K*, the number of scale points. Numerous psychometric studies suggest that more scale points are better in terms of information recovery, but only up to about seven points. Additional scale points do not provide substantially more information about the underlying attitude, and run the risk of confusing the consumer. A related question is whether the scale should have an odd or even number of points. An odd number allows for a middle (neutral) category that can be used if the consumer is ambivalent. In contrast, an even number of points force the consumer to choose one end of the scale or the other. A final question is whether or not the consumer should be allowed to opt out of responding to a Likert scale by selecting “Don’t Know.” Failure to

supply a “Don’t Know” option can lead to increased measurement error by uninformed consumers. However, allowing “Don’t Know” creates missing data problems in the subsequent statistical analysis. Marketing research consultants tend to favor an odd number of response categories without an option for a “Don’t Know” response. These choices, however, should be on the basis of the needs of the particular researcher.

Semantic differential and Stapel scales. The remaining two scales are variants of each other. The semantic differential scale is a bipolar scale for which the consumer rates an entity on some characteristic. For example, we could ask consumers to rate Wal-Mart along a 5-point scale, where 1 indicates “Great Service” and 5 indicates “Poor Service.” The words on the endpoints are intended to convey the fact that the researcher is interested in the position of Wal-Mart on a continuum of service quality. In practice, problems arise if the consumer does not view the two endpoints as opposites.

As shown in Table 2, the Stapel scale is a semantic differential scale with an even number of response categories and the endpoints not labeled. The Stapel scale was developed, in part, to escape the problem of endpoint definition and to allow easier survey administration over the phone. Hawkins, Albaum, and Best (1974)

provide empirical evidence that the semantic differential scale and the Stapel scale can provide comparable information when the number of scale points in the two administrations is the same. The principal challenge of the Stapel scale is developing labels (such as “Service” in Table 2) that accurately convey the attribute that the researcher wishes to measure.

SCALE DEVELOPMENT

Often, the objective of the research study is to develop a measure of some sort of consumer characteristic (such as deal proneness) or consumer perception of some product characteristic (such as service quality of a fast food restaurant). To improve the accuracy of the attitude measure, researchers often ask the same question in a variety of different ways, and then average the answers to provide a final score. The process of selecting the items to be included in a composite scale is known as *scale development*.

Item generation. The first step is the generation of items to include in the survey. Here, the researcher must make a key decision. Is the objective of the research *person-centered* measurement or *object-centered* measurement? In the context of marketing research, *person-centered measurement* is defined as the development of an attitude measure for each consumer in the study. As such, the researcher will need to ask each consumer a number of related questions. In contrast, *object-centered measurement* is defined as the measurement of a characteristic of a product from a market-level perspective. For

an object-oriented measurement application, it suffices to ask each consumer one question, and then to average the answers across all consumers in the study. To avoid confusion in the remainder of this article, we assume that the researcher is primarily interested in person-oriented measurement.

Item generation is a creative task that requires the researcher to understand the meaning of the attitude under study. Using a *deductive* (top-down) approach, the researcher would carefully define the construct under study and then attempt to create items that measure different aspects of the construct. Scales might be based upon previous research using the same construct. In contrast, using an *inductive* (bottom-up) approach, the researcher might discuss the topic with focus group consumers, and then use the focus group transcript as a basis for item generation.

Most scales are constructed using both deductive and inductive reasoning. Consider the deal proneness scale in Table 3, taken from a recent study by Wirtz and Chew (2002). The six items are all Likert items, having a 7-point scale from 1 (strongly disagree) to 7 (strongly agree). Because deal proneness is a relatively straightforward attitude, it is possible for a researcher to simply generate these types of items. However, talking to consumers in a focus group setting could provide additional insights that might suggest other items for inclusion. It should be understood that the six scales in Table 3 are just a subset of the original set of items generated in the research process. As we explain next, it is

Table 3 Deal proneness scale items.

| |
|---|
| 1. Redeeming coupons and/or taking advantage of promotion deals make me feel good. |
| 2. When I use coupons and/or take advantage of a promotional deal, I feel that I am getting a good deal. |
| 3. I enjoy using coupons and/or taking advantage of promotional deals, regardless of the amount I can save by doing so. |
| 4. I am more likely to buy brands or patronize service firms that have promotional deals. |
| 5. Coupons and promotional deals have caused me to buy products and/or services I normally would not buy. |
| 6. Beyond the money I save, redeeming coupons and taking advantage of promotional deals give me sense of joy. |

All items are measured using 7-point Likert scales (1 = strongly disagree, 7 = strongly agree). Conceptual and methodological details concerning the development of this scale can be found in Wirtz and Chew (2002).

6 itemized rating scales (Likert, semantic differential, and Stapel)

essential to generate more items than are really needed, in order to select only those items that best measure the attitude under study.

Scale construction. Scale construction is a process of evaluating the properties of an attitude scale using data collected from a representative sample of consumers. The psychometric theory of mental test scores (Lord and Novick, 1968) suggests two key considerations: *reliability* and *validity* (see also RESEARCH RELIABILITY AND VALIDITY). Simply put, a scale is reliable if the measurement error of the scale is small. A scale is valid, if it actually measures the underlying attitude that the researcher intends the scale to measure. It can be shown that high reliability is a necessary condition for high validity. However, it is entirely possible to have a highly reliable scale that is completely invalid.

The usual procedure is to generate a large number of items, construct a questionnaire based upon these items, and then survey a *representative sample* of consumers. The sample should be drawn from the same type of consumers who will be studied after the scale is finalized. For example, college students should not be used during scale construction if the scale is intended for use among middle-aged consumers. To avoid response biases, some items should be reverse coded, so that high agreement (on a Likert scale) or positive affect (on a semantic differential scale) is not always on the right-hand side of the scale (with an associated high scale number). Subject to limitations of respondent fatigue, the larger the list of potential scale items, the better.

Once the survey is administered, the researcher then must do a series of technical checks, both to weed out unacceptable items, and to ensure that the scale represents a unidimensional construct. It is here that the ordinal versus interval measurement controversy noted earlier becomes important. The usual practice is to simply assume interval level measurement of the individual scale items, and then to employ regression-based statistical tools to analyze the properties of the proposed attitude scale. Later in this article, we briefly discuss alternative approaches that rely only upon the ordinal properties of itemized rating scales.

At this point, the researcher is interested in two issues. The first is whether or not all

items measure the same underlying attitude. This can be examined by estimating a correlation matrix for all items (using the survey responses) and then analyzing the correlation matrix using *exploratory factor analysis* (see EXPLORATORY FACTOR ANALYSIS). It is beyond the scope of this article to adequately explain the factor analytic model in any detail. Intuitively, factor analysis is a way of exploring the structure of a correlation matrix. The approach assumes that the estimated correlations arise from two sources: underlying attitudes that the consumer uses answer the scale items on the questionnaire, and random error because of the measurement process. The factor analysis model first adjusts the correlations for the reliability of individual scale items, and then develops an eigenvalue decomposition of the adjusted correlation matrix. If a one factor solution emerges, then the researcher can be confident that all items measure the same attitude. Usually, a one factor solution does not fit the correlation matrix. In this case, the researcher deletes unacceptable scale items until a one factor solution emerges. This is the basis of the general recommendation that the researcher generates a large set of items for consideration in scale construction.

The second issue is the issue of reliability. Formally, *reliability* is defined as the proportion of the observed variance in the scale rating that is owing to the true score (i.e., the underlying attitude the researcher is attempting to measure). Reliability can be measured directly by having the same group of consumers take the survey twice, and then correlate the rating selected for the same item across the two occasions. This procedure is both difficult to administer and assumes that consumers do not remember their prior ratings. Instead, the usual procedure is to examine the variances and intercorrelations among the items of the proposed attitude scale and then compute a measure of reliability known as *Cronbach's alpha* (Eagly and Chaiken, 1993).

Generally speaking, an alpha of 0.70 or higher is considered acceptable in scale construction. Adding more items to a scale increases reliability. However, psychometric theory indicates that attitude scales having 5 to 7 scale items are sufficiently accurate for most research purposes, as long as the Cronbach's alpha cutoff is attained. Wirtz and Chew (2002) report that the 6-item

Table 4 Hypothetical multitrait-multimethod matrix.

| | | <i>Semantic Differential</i> | | | <i>Stapel</i> | | |
|-----------------------|---|------------------------------|--------|--------|---------------|--------|--------|
| | | S | E | R | S | E | R |
| Semantic differential | S | (0.93) | | | | | |
| | E | 0.47 | (0.90) | | | | |
| | R | 0.21 | 0.35 | (0.91) | | | |
| Stapel | S | [0.59] | 0.23 | 0.21 | (0.80) | | |
| | E | 0.20 | [0.60] | 0.13 | 0.15 | (0.87) | |
| | R | 0.22 | 0.24 | [0.68] | 0.33 | 0.10 | (0.83) |

scale shown in Table 3 has a Cronbach's alpha value of 0.73.) It is important to understand that a high Cronbach's alpha does not necessarily imply that the items form an unidimensional scale. Factor analysis is always necessary to verify scale dimensionality.

Scale evaluation. The final step in scale development is validity. As noted earlier, a valid scale measures the actual attitude that the scale was intended to measure. A variety of different ways of assessing validity exist. The two most important are *convergent validity* and *discriminant validity*. Convergent validity is the idea that two scales that purport to measure the same attitude ought to yield scores that are highly correlated. Discriminant validity is the opposite notion: scales which purport to measure different (unrelated) attitudes ought to yield scores that are not highly correlated. As is apparent from this description, validity requires the researcher to have a good theoretical understanding of the relationship among the different consumer attitudes being measured.

One of the most stringent tests of validity is the multitrait-multimethod (MTMM) analysis developed by Campbell and Fiske (1959). To understand the approach, consider the following hypothetical scenario. Suppose that a researcher develops two versions of a multiple-item scale to measure consumer perceptions of brand personality: the attribution of human personality traits to brand names. Three scales are created, for seriousness (S), excitement (E), and ruggedness (R). The researcher decides to develop one measure of brand personality using semantic differential scales, and another using Stapel scales. Two surveys are done, one month apart,

during a period of time in which the advertising campaigns in the market undergo no changes in message. The same consumers are surveyed at both time points. The goal of the researcher is to validate the three personality scales.

A hypothetical MTMM matrix for this scenario is shown in Table 4. The matrix is symmetric with only the bottom half shown. Along the diagonal (in parentheses) is the Cronbach's alpha reliability measure for each type of scale. In this case, the semantic differential scale apparently has less measurement error than the Stapel scale. The correlations in brackets [*x*] are measures of convergent validity: the correlation between two scales attempting to measure the same aspect of brand personality. The remaining correlations reflect method variance: the observation that different attitude measurements constructed using the same type of itemized rating scales will be positively correlated. The overall pattern in the matrix suggests that semantic differential and Stapel scales for the same personality characteristic measure the same attitude (convergent validity) and that three brand personalities are distinct attitudes (discriminant validity).

Another type of validity analysis concerns marketing research conducted in various countries (such as the member countries of the European Union). Although itemized rating scales can always be used, survey items and respondent instructions must be translated into different languages. In this context, there are obvious questions about whether attitudes measured in one country (say, Spain) can be compared to supposedly identical scales (except for language) in another country (say, Italy). Steenkamp and Baumgartner (1998), using the statistical tools

8 itemized rating scales (Likert, semantic differential, and Stapel)

of *confirmatory factor analysis* (Brown, 2006), show how to evaluate whether scales in different countries measure the same attitudes. Assuming that the scales pass this test, they further show how to adjust the scales so that meaningful cross-country comparisons can be made.

LATENT VARIABLE MODELS

As noted earlier, one of the running controversies in the attitude research community is whether or not itemized rating scales can be considered as interval level measurement. Advances in psychometrics in the last 40 years allow researchers to develop continuous measures of attitudes while assuming that rating scales only have ordinal properties.

The general approach is called *latent variable modeling* (Skrondal and Rabe-Hesketh, 2004). Simply put, a latent variable is a random variable whose outcomes cannot be directly observed. However, these outcomes impact observed variables in a known way. In psychometrics, latent variables are found in *latent trait theory* (LTT), a way of conceptualizing how people respond to rating scale items (Lord and Novick, 1968). In the context of itemized rating scales, LTT assumes an unidimensional attitude continuum in which consumers have an attitude score at a specific location, and the itemized rating scale imposes cut points along the same continuum. LTT assumes that the consumer attempts to report the interval along the continuum in which his or her attitude lies, but the reporting is subject to random errors with a known distribution.

Researchers working with marketing survey data have demonstrated that the LTT technology allows the simultaneous calibration of rating scale cut points and consumer attitudes (Balasubramanian and Kamakura, 1989). This work has interesting implications for optimal scale construction, including the idea that rating scales can be optimally tuned to each individual by selecting only those items that maximize the accuracy of the attitude measure generated by the scale. Such *tailored tests* are possible if respondents are seated in front of a computer terminal.

One of the most interesting recent developments in scale construction is the *partial least squares* (PLS) algorithm (Geladi and

Kowalski, 1986) applied to latent variable systems. Traditionally, attitude scales are constructed without regard to their ability to predict other attitude scales. Indeed, the entire literature on scale validity (discussed earlier) is based upon the notion that scales should be constructed in a logically rigorous fashion and then validated by computing correlations with other independently generated scales. The PLS algorithm makes it possible to scale two sets of rating scales simultaneously in such a way that the correlations among the underlying latent attitude scales are maximized.

This approach is the methodological foundation of the American customer satisfaction index (ACSI), a satisfaction measurement system developed at the University of Michigan (Fornell *et al.*, 1996). Data collection for the ACSI consists of consumer surveys tapping aspects of customer satisfaction in a variety of goods and services, all done using 10-point Likert scales. The ACSI statistical analysis yields six continuous attitude measures (perceived quality, customer expectations, perceived value, customer complaints, customer loyalty, and overall customer satisfaction). Conceptually, the ACSI methodology creates attitude scales with known validity and reliability characteristics, while only assuming that the Likert scale inputs have ordinal measurement properties.

SUMMARY

Itemized rating scales are ordinal scales used to measure consumer attitudes. Three types of scales are commonly used in marketing research: Likert, semantic differential, and Stapel. Likert scales ask consumers to agree or disagree to declarative statements. Semantic differential and Stapel scales ask consumers to rate entities along an ordered continuum. Attitude scales in marketing research are usually created as multiitem scales, which are analyzed using regression and factor analytic methodologies to examine reliability and validity. Newer analysis methods based upon latent variable models assume that itemized rating scales only have ordinal measurement properties, but allow the construction of continuous measures of consumer attitude.

observation methods

Robert V. Kozinets

DEVELOPMENT AND DEFINITION OF OBSERVATION METHODS IN MARKETING RESEARCH

For well over a half century, marketers have been interested in understanding the bases of brand loyalty. Marketing researchers have responded to this need by developing methods and techniques designed to illuminate the reasons that consumers show their loyalty to particular brands in marketplaces that are, for the most part, distinguished by their lack of differentiation. In the period from the 1930s to 1960s, motivation research was an extremely important set of techniques used by the marketers at major corporations to give them a competitive edge for differentiation (*see* MOTIVATION RESEARCH). These techniques were built around forming deep understandings of the way that consumers feel about and interact with products and services. Observation methods grew out of the recognition that gaining an understanding about the reasons for consumers' behaviors was critically important to competitive and proactive marketing management. To gain this realistic understanding, marketing research required an orientation that considered product and brand usage in a natural, holistic, and cultural context (Sunderland and Denny, 2007). This meant observing actual product purchase and consumption where it occurred (*see* ETHNOGRAPHIC RESEARCH). Observation methods were specially adapted to this reality (Angrosino, 2007).

Observation methods are defined as qualitative marketing research methods in which researchers view, record, and then analyze the manifest actions of consumers as they engage in some market-related activity. The range of observations and data is considerable. Observation methods would cover the mass observations and measurements of large groups of anonymous people (*see* PERSONAL OBSERVATION). They would also encompass the placing of cameras in public places or in private areas. Analyses of the data from observation methods would also possess a considerable variety of forms,

ranging from automatic counters calculating basic behaviors to extremely intimate investigations where researchers intrusively live with consumers in order to carefully observe and record their behaviors.

ORIGINS OF OBSERVATION METHODS

Observational research and its methods originated in the anthropological method of ethnography (Angrosino, 2007). *Ethnography* is an anthropological method that studies members of a culture in depth through the techniques of participant observation (*see* ETHNOGRAPHIC RESEARCH). Ethnographers conduct naturalistic research – research that is done in a naturally occurring context. Laboratory experiments and pen-and-pencil surveys and tests would not be considered naturalistic (*see* VALIDITY IN EXPERIMENTATION). An ethnographer's insights are gathered from “in-the-field” observations of people as they go about their daily lives (Sunderland and Denny, 2007). Although ethnography was developed originally for studies of distant, “primitive” tribes, it was applied to urban cultures in the early decades of the twentieth century. By the second half of the twentieth century, the advantages of ethnography had been recognized by the marketing and marketing research communities, and dozens of specialized firms and practitioners turned their unique observational skills toward observation of consumers in their native habitat (Angrosino, 2007). Observation methods in marketing research thus specialize, adapt, and then apply the observational techniques developed by anthropologists.

As observation-method practitioner Bill Abrams (2000, p. xxi) puts it, “there is no research tool like observational research for providing personal, up-close insight. No other research methodology allows you to go through your consumer's pantry, stand there while he/she flosses his teeth, or watch while he/she suffers and gets relief from an upset stomach or be there when a new computer owner gives up trying to get it to work with his/her printer at one in the morning.”

This level of closeness to the consumer offers invaluable intelligence for marketers. It is difficult, but extremely valuable to understand how

consumers actually behave in certain situations, rather than simply ask them about how they behave or intend to behave (see PERSONAL OBSERVATION). As we know from many statistical studies, consumers' memories and recollections about their behavior are unreliable, as are measurements of their intentions (see RESEARCH RELIABILITY AND VALIDITY). If, for example, we were to ask the average large American family how many breakfast cereals are in their kitchen cupboard, or how many different bottles and brands of shampoo are in their bathrooms, we would be extremely unlikely to get an accurate answer. Yet, marketing researchers commonly ask such questions in their surveys and in focus groups. Observation methods offer an alternative to these after-the-fact methods of data collection. Instead of asking these questions, the researcher gains access to the consumers' homes and actually burrows through their kitchen cabinets, bathroom counters, bedroom closets, garage, and even garbage cans looking for the details and the clues about what products actually have been purchased and are in use, and what behaviors actually occur (Sunderland and Denny, 2007). With important corporate decisions on the line, observation methods can be an extremely powerful tool for revealing actual behavior.

PROCEDURES AND EXAMPLES OF OBSERVATION METHODS

Consider the needs of a hypothetical fast food company seeking marketing research about traffic patterns. Let us say this company, Joe's Burgers, is trying to make a decision about which location to lease to open a new restaurant. Observation methods could be brought to help make this decision. An example would be to hire someone who simply stood with a counter and stopwatch and manually counted the number of cars that passed by particular intersections of the city. Moving from one intersection to another and sampling at several different times of the day would yield comparisons that could help the fast food company choose the right location for its business. Another simple example would be to conduct market research at a cross-border shopping mall to understand how many consumers drive across the border to shop there. A survey researcher might consider asking a sample of

400 or more randomly chosen shoppers about their origins. A researcher using observation methods, however, would simply head to the parking lot. There, the researcher would note the license plates, using the actual cars in the lot to determine in which country the shoppers reside.

Observation methods can also involve the installation of cameras, or the use of existing cameras – such as the many closed-circuit television (CCTV) cameras in metropolitan areas. In the case of installed cameras, consumer homes that are of interest to the marketing researchers are chosen. The consumers are compensated for installing a camera in a particular room (let us say it is the kitchen). The camera stays on and records the consumers' behavior 24 hours a day. The resulting videotapes are analyzed carefully, sometimes even frame-by-frame for the intelligence and understanding they can provide of consumers' habits (Angrosino, 2007).

At their most intimate and most revealing, observation methods can involve an in-home interview and observational session or sessions. Observational interviews (also called *in-home interviews* or *ethnographic interviews*) will take place in a naturalistic setting, namely, in any setting that is familiar to the consumer (see FOCUS GROUPS AND DEPTH INTERVIEWS). They do not usually take place in the presence of other consumers or behind one-way glass, as with focus groups. Observations of product use and the consumer interview take place in the location where the product is usually bought and used. In those natural settings, such as consumers' homes, favorite stores of the consumer, or consumers' workplaces, the consumer tends to relax and generally finds it much easier to do and say what they usually do and say (Sunderland and Denny, 2007).

So, for example, in a study of toothpaste, the observation methods interview would take place in the consumer's own bathroom. It would also take place at the usual time when the consumer uses the product – in this case, first thing in the morning or the last thing before bed at night. After gaining permission from the consumer, and ensuring consent, the interviewer would “tag along” while the consumer gets ready for bed, or wakes up (usually this requires financial compensation). During the interview, the researcher might investigate the area and related

areas in the home. For a toothpaste inquiry, the researcher might look around the bathroom and examine the toothbrushes, mouthwash, and other oral hygiene products that might be on the counter. The researcher might also investigate the cupboards where extra tubes of toothpaste and toothbrushes are stored.

The interview is recorded, oftentimes with an audio recorder. The researcher usually keeps a notepad nearby and jots down notes for future reference as well as to immediately follow up on interesting phrases or topics raised by participants during the interview. Still pictures are often taken and, increasingly, video cameras are used to capture the details as well as simply to record the interaction. Procedurally, Abrams (2000) says that it is very important for the interviewer to maintain a relaxed, laid-back, and easygoing attitude during the interview. At the same time, the interviewer also uses a thoroughly designed and precise interview guide to ensure that all questions are being answered. As in depth and ethnographic interviews, the researcher wants to gain the trust of the consumer and engage in genuine rapport.

Observation research can be conducted as a team. Usually, a small team of marketing and research practitioners enter the homes of a small number of research participants. Usually, there are between 10 and 20 participants scheduled for such a study. The team carefully observes, films, records, and take notes of the individuals and/or the family going about their consumption or shopping behaviors, while trying to stay as unobtrusive as possible. The team then regroups and debrief together in an office space, a restaurant, or, perhaps, a hotel room. They go over their notes and make plans for the next session. At the end of this “blitzkrieg” of “home invasion” research, which usually lasts three to five days, the team will write their findings and present recommendations for action to the management (Abrams, 2000).

With a skilled researcher, consumers will start to relax, act naturally, and disclose their opinions and preferences within just a few minutes. Oftentimes, family pressures and politics are discussed as motivating factors behind many decisions. The researcher rapidly becomes privy to confidential matters, such as husbands’ deep-seated need for their wives’

approval, wives’ deep-seated need for their husbands’ approval, parents’ deep-seated need for their children’s approval, and even some consumers’ “dirty little secrets” that they do not floss/brush/comb/clean nearly as often as people think they do!

Another common observation method used to audit and research retailers is the use of mystery shopping or the “mystery consumer.” In the mystery shopping methodology, researchers enter a retail environment posing as ordinary consumers. They gather specific – often highly specific – information about the quality of the retail service provided, as well as particulars of product choice, display, lighting, and other details. After leaving the retail environment, these hired professional observers report their findings either to other researchers who aggregate the data or to the final client.

VIDEOGRAPHY

The “videography” technique is gaining acceptance and popularity (Belk and Kozinets, 2005). Videography allows marketers to access, analyze, and research the actual actions of consumers as they go about their consumption in any naturalistic context (*see* PERSONAL OBSERVATION). The expenses associated with producing and distributing broadcast-quality video have drastically fallen as digital technology has advanced over the past decade. These developments have led marketing researchers to enter the domain of filmmaking once reserved for documentary journalists.

The most common use of videography is the videotaped individual or group interview, conducted either in a research facility or in a field setting (Belk and Kozinets, 2005). Videotaped interviews offer the powerful advantage of capturing body language, distance, motion, and other temporal and spatial dimensions of human behavior and social meaning. The second most common use of video is as a form of observation method: using the video camera to record naturalistic observations. In recording naturalistic observations, the videographer is more interested in capturing what people actually do rather than what they say about what they do (Kozinets and Belk, 2006).

Sometimes, a camera person accompanies the researcher, usually with a small camera and a lavalier or a wireless microphone. Increasingly common is the videographic technique where the interviewer is also the cameraperson. The filming techniques that are usually used in observational research originate from a school of film known as *cinéma vérité*, which was developed by documentary filmmakers in the United States and France in the late 1950s. The theory behind *cinéma vérité* is for the filmmakers to become as unobtrusive as possible. In its application as a form of consumer research, the idea is for consumers to get used to the presence of the videographer. As the videographer starts to naturally blend in to the context of the consumers, he or she can start to capture surprising revelations as well as genuinely mundane aspects of daily life.

Variants of videography based on naturalistic observation are increasingly common. Sometimes, videographers provide these research participants with a camera and ask them to directly capture and videotape their usage of a product or a service. This autobiographical technique has distinct advantages over researcher-conducted video observation. It is considerably less of an intrusion into the participant's life and is also less directed by researcher motives and needs, perhaps allowing new insights to come to the fore (Kozinets and Belk, 2006).

Unobtrusive observations caught on video, such as store camera data, are also commonly used as a form of videographic observation method. Sometimes, these observations can use concealed video equipment, a practice that must be used cautiously as it can be unethical. Like all observation and qualitative research, videographic data analysis follows the basic principles of interpretive analysis, from coding, to grounded theory construction, comparative case analysis, and hermeneutic circling. Video insights can be generated in a holistic fashion, or can occur through a bottom-up process that codes and classifies video capture on a frame-by-frame, event-by-event, or moment-by-moment basis.

Videography is a compelling observation method with many advantages, which is why it has become an increasingly frequent accompaniment to traditional marketing research

interviews and ethnography. Videography captures the moment and allows it to be analyzed by researchers. Not only this, but it also can be made portable, shared with other researchers, and incorporated into training materials and research presentations. With audiovisual research, the marketing research is able to capture more of the subtle temporal, social, and spatial dimensions of human behavior, including the intricacies of human body language. The resulting research presentation to management is often emotional, vibrant, and humanizing in a way that slide presentations and written reports simply cannot match (Belk and Kozinets, 2005; Kozinets and Belk, 2006; Sunderland and Denny, 2007). Marketers watching a well-done videography often gain a sense that they have actually spent time with their consumers, experiencing their behaviors alongside them.

MARKETING AND RETAIL RESEARCH USES OF OBSERVATION METHODS

Observation methods have been used to develop insights for strengthening the brand differentiation of a variety of products and services. In a competitive marketplace, even small differences in perception or/and function can be critical to gaining market share. It was observational research conducted by a cereal manufacturer that led to a repositioning of a common O-shaped cereal as a snack food for infants. In observations of breakfast cereal use, observational researchers discovered that mothers would often pack a plastic bag of these oval-shaped oat cereals to take it "on-the-go" as finger food to feed their young children out of the home. The finding was new to the cereal manufacturer. Focus groups, surveys, and personal interviews had not revealed it. In response, the manufacturer began marketing the cereal as a finger food for young children, promoting it in giveaways and children's books, and offering convenient plastic containers with prominent branding on them to replace mothers' inconvenient and flimsy plastic bags. The result was incremental sales for the manufacturer in an extremely competitive marketplace, better targeting at a new segment, and stronger branding for the cereal that has continued to the present day.

Observational research has also been found to be extremely helpful in generating insights and identifying areas of untapped opportunity for new-product development. By watching how consumers use – and misuse – existing products, and by speaking to them during their product use about their frustrations, unfulfilled needs, and dream or fantasy products, valuable raw ideational material is generated (*see* EXPLORATORY RESEARCH). These consumer insights can then be translated into working prototypes, tested on representative samples, subject to cost-benefit analyses, and eventually turned into successful new products.

Consumers in observational studies often generate valuable ideas spontaneously. Observational studies of how consumers “fix” the problems that they find in products often lead to new ideas for innovations (Sunderland and Denny, 2007). For example, observational research on how people used condiments at home revealed a common problem. The problem revealed itself once consumers got close to the bottom of a squeeze bottle of ketchup or mustard. At that point, the last 20% or so of the bottle was difficult to squeeze out. What do consumers do? They turned the bottles upside down, of course, developing various contraptions to balance them in their rotated positions. When engineers at the food company studied pictures of these almost-toppling bottles, they came up with a packaging solution to the problem. The solution was to design the bottles with a flat top so that, once enough of the condiment had been squeezed out of the bottle, it could be easily turned over and stored. The result was a new-product packaging innovation, competitive differentiation in a highly competitive category where steady gain was being made by private label brands, stronger consumer packaged goods branding, and a consumer problem solved, all courtesy of observation methods.

Observation methods also help retailers to understand the pain points and difficulties faced by shoppers as well as the many opportunities for improving consumers’ shopping experiences. In a hidden camera study of a hardware store, the confusion on consumer faces and in their body language is almost comical. The consumers are faced with a relatively simple task such as

matching the desired screw with its counterpart from the store. Yet with dozens of choices, and no organization or system for the shelving, the task was nearly impossible for most people. The observation methods study resulted in the hardware retailer designing a shelving system with clearly marked differences, enabling the average consumer to quickly and efficiently find the screw that they were looking for.

Consultant Paco Underhill (1999), the founder of retail marketing research agency Envirosell, relies almost exclusively on observation methods to generate insights for clients such as Wal-Mart, Saks Fifth Avenue, the Gap, Hallmark, and Starbucks. Underhill’s research consists of careful tracking of what he calls “the science of shopping.” “Essentially, trackers stealthily make their way through stores following shoppers and noting everything they do. Usually, a tracker begins by loitering inconspicuously near a store’s entrance, waiting for a shopper to enter, at which point the ‘track’ starts. The tracker will stick with the unsuspecting individual (or individuals) as long as the shopper is in the store (excluding trips to the dressing room or the restroom) and will records on the track sheet virtually everything he or she does. Sometimes, when the store is large, trackers work in teams in order to be less intrusive” (Underhill, 1999, p. 13). In addition to counting, recording, and measuring the motions and behaviors of shoppers during their shopping trips, the trackers also record their own observations and insights in a set of field notes. These field notes are intended to capture the details of consumers’ shopping behavior, making informed inferences based on the recorded observations (Underhill, 1999).

One of the principles discovered by Underhill and associates and recorded in his book about “the science of shopping” is something that he terms *the butt-brush effect* (Underhill, 1999, pp. 17–18). In a study that they conducted for Bloomingdale’s in New York City, the observation researchers had a camera recording one of the main entrances. The camera also caught the next sales rack that was positioned on a main aisle near the entrance. As they reviewed the recordings, they noticed that shoppers approached the tie rack and stopped to look at the ties. However, because the aisle was near the entrance, people

who were heading out or in the store would bump the tie shoppers. After they were jostled once or twice in this manner, most of the shoppers would abandon their search for neckwear. Underhill's group concluded that shoppers did not like being touched, brushed, or bumped from behind and would cease their shopping in order to avoid it. This was true especially of women, but also of men. Upon further investigation with Bloomingdale's, it turned out that sales from the tie rack were lower than they had expected. Underhill's group hypothesized that "the butt-brush factor" was to blame. Bloomingdale's management moved the tie rack shortly after the presentation of results and a few weeks later sales from that rack apparently rose quickly and substantially. The results of this observation-method-based finding underscored the importance of positioning sales displays so as to allow freer movement and less unintentional bodily contact between people.

Another insight into consumer motivations and psychology was gained from retail use of observation methods. Underhill's group was conducting a supermarket study for a manufacturer of dog food. Observing the pet food aisle, the group noticed that dog treats tended to often be picked out by senior citizens and children. The group asked itself why this was happening. Their answer was that elderly people considered the dogs to be akin to their grandchildren, and wanted to spoil them. Similarly, children had fun feeding treats to dogs; it was almost like playing with a toy. Parents would buy dog treats for their playful children, giving in to their whims the same way they would indulge the children themselves with treats. The retailing implication came in regarding the placement of the dog treats. The pet treats were typically located near the very top of the supermarket shelves. In that location, children and elderly people often found it difficult to get at them. The advice coming out of this observational research was to move the treats where they could be more easily reached by older people as well as children. According to Underhill's (1999, p. 19) book, "the client did so, and sales went up overnight."

TECHNOLOGICAL OBSERVATION METHODS AND TREND SPOTTING

Internet and information communications researchers are among the pioneers of a new generation of observational research (Angrosino, 2007). Information monitors such as the Nielsen Ratings and TiVo have been working on observational technologies to unobtrusively measure people's media viewing habits. Tracking and following click stream data – which often links to individual IPs or Internet protocol addresses – is one sophisticated way to understand what people actually do online. A large number of social media companies, such as Google, Flickr, Amazon.com, and FaceBook have benefited from the ability of the Internet to track what people click on or actually "do." Technological tools applied to the online environment allow us to closely monitor and measure what people actually buy online, finding the patterns of online purchase or e-commerce. Trend-watching and trend-spotting companies are using new technologies to get more rapid feedback on the latest changing trends. Furthermore, the millions of conversations on the Internet have become an important source of data for marketing researchers using technologically enabled observation methods like data mining, thematic analysis, and netnography.

The Neilson Online measurement systems now reveal consumers' online viewing habits, for example, revealing the most popular streamed television shows and web sites. TiVo, the company that sells the digital video recording device and its related online service, is also pioneering methods of collecting data about television viewers from their product. In 2004, TiVo was the first in the primary source of information about how many people actually saved or "TiVoed" the image of Janet Jackson's exposed breast during SuperBowl XXXVIII. Although TiVo does not store any individuals' viewing records, and viewers can opt out of having their own personal data collected if they wish, TiVo receives a steady stream of information or data from its viewers, and it has begun selling the data to the television industry through various commercial research partnerships.

In another example of a technologically mediated use of observation methods, Look-look, a trend-forecasting firm has recruited thousands of young people between the ages of 14 and 30 to act as amateur trend spotters and observers. These consumers send in a constant stream of market-based information by instant messenger and pagers. The research firm conducts on-the-spot observational research designed to try to understand the trends and motivations of younger consumers. In this research, these hand-picked field correspondents also upload images from digital cameras that can record events such as parties, concerts, and sporting events. Information flow also goes both ways. Similar trend-spotting firms are constantly on the lookout, such as Boston-based BzzAgent, a word-of-mouth marketing firm that not only distributes products to its group of “influentials,” but also monitors their opinions to stay on top of the latest trends.

With well over 100 million consumers as members of online communities globally, massive amounts of public interactive data exist on the Internet. For over a decade, marketing researchers have been devising methods to try to analyze and understand this information. When we consider the fact that consumer-to-consumer conversations are naturally occurring on the Internet, these computer-aided observational techniques offer a powerful combination that is both naturalistic and unobtrusive. Companies like Nielsen Buzzmetrics and MotiveQuest have pioneered sophisticated tools to analyze these online conversations. Their programs and analysts mine the Internet for the data, then code and analyze the data to help marketing managers understand the general complexion of Internet “chatter.”

Another observation method that has developed as a direct outbranching of ethnography with the power of the Internet is called *netnography* (Kozinets, 2002). Netnography is ethnography adapted to the unique contingencies of the online environment: technological mediation, anonymity, textuality, automatic archiving of messages, and invisible public audiences. Netnography can potentially be conducted in a manner that is entirely unobtrusive. This sets netnography apart from other observational techniques such as in-home observation and

ethnographies, as well as from more popular methods like focus groups, depth interviews, and surveys.

In terms of time expenditures, expending on recruitment, personal meetings, traveling, transcribing observations, conducting personal interviews, and writing handwritten field-note data, netnography is far less time consuming and elaborate than traditional, in-person observation methods such as in-home observational research interviews and ethnography. Netnography provides marketing researchers with a window into naturally occurring behaviors, such as community discussions about different products, services, lifestyles, or experiences. Because it is conducted using observations and interactional data collected from people in a context that is not designed or artificially fabricated by the researcher, netnography is less intrusive than focus groups and personal interviews. The type of information provided in a netnography and the ease of its collection means that netnographic research can be more timely than traditional, in-person surveys, interviews, and focus groups (Kozinets, 2002). As an observational technique of the naturalistic communities emerging and increasing on the Internet, netnography’s potential is being recognized by global businesses and its popularity is growing. However, because of its cultural approach, netnographic data can be as difficult to interpret as ethnographic data. In many cases, netnography does not necessarily allow us access to what consumers actually do with particular brands, products, and services. It only allows us to “overhear” the naturalistic conversations that they have pertaining to them.

LIMITATIONS OF OBSERVATION METHODS

The limitations of observation methods tend to arise from their small sample sizes (*see STATISTICAL APPROACHES TO DETERMINING SAMPLE SIZES*). Because this is inductive research based upon the detailed analysis of very small groups of people, it is important for marketers to test these insights further to find out if they are idiosyncratic and unique, or broad and generalizable (*see HYPOTHESIS TESTING RELATED TO DIFFERENCES – PARAMETRIC TESTS*). If observation methods are appropriately analyzed and interpreted,

their conclusions will be carefully verified on broader samples using causal methods. These investments in verification should be made before other costly investments in production and marketing are made.

Because it tends to be time intensive, and to involve significant researcher skill, some observation research can be quite expensive to conduct. However, new technological forms of observation can be quite inexpensive to perform. Because observation methods now include such a vast diversity of forms, observation research no longer means sending sole researchers out into the field of consumers' homes to conduct weeks of grueling in-home interviews (see EXPLORATORY RESEARCH). Many companies are now finding that they can tailor an observational research plan to their specific needs.

In addition, observation methods provide personal, meaning-laden, symbolic, cultural-level data rather than statistical forms of data. Human actions and words require careful and skilled interpretation. Observation methods, like ethnography and many other methods (even quantitative ones) depend upon the skill of the researcher utilizing them (see ETHNOGRAPHIC RESEARCH; EXPLORATORY RESEARCH; FOCUS GROUPS AND DEPTH INTERVIEWS; PERSONAL OBSERVATION). Some researchers might walk into a frat house filled with spray-painted beer bottles and see nothing but a mess. Others might see an opportunity to develop a new brand of beer that caters to a new, wild and free, do-it-yourself target segment, and their creative ethos. The skill of the observational researcher is critical to the interpretation, and can be the single, most important

factor determining quality outcomes from the research. Nonetheless, in many cases, the raw data that is generated from observation methods offers something uniquely valuable: authentic observations of real people as they actually use products and services. Without the genuine data of real peoples' consumption generated by observation methods, true marketing insights and breakthroughs may be much harder to find.

questionnaire design

Jagdish Agrawal

INTRODUCTION

Every day, managers are confronted with uncertainty regarding the future course of events and the possible outcomes of a decision. For example, a manager may need to react to new information provided by one of his salespeople that a major competitor has been offering deep discounts to its customers. Or, she/he may be confronted with the option to choose one of three different countries for a major investment to build a new plant in order to cut manufacturing costs. These uncertainties, also known as *problems*, require decisions. Some problems require an immediate decision based on whatever information is available at that time; others may require collecting new data from a variety of sources.

Conducting surveys with the help of a questionnaire is perhaps the most dominant method of collecting data for academic research, public institutions, and business organizations. A questionnaire affects both the quality and quantity of data. A poorly designed questionnaire will cause errors or bias in research findings rendering the results of the survey worthless for decision making. In addition, if the survey is not properly designed, it may not motivate respondents or it may discourage them from completing the survey resulting in the lack of adequate data to make valid inferences regarding the topics of research. Although it is perhaps impossible to design a perfect survey, we can avoid mistakes commonly made when designing a survey and improve both the quality and the quantity of data collected from the survey. The steps required to help achieve this objective are discussed in the following.

Identify the information needed. Before conducting any kind of survey, it is very important either to list all the questions that need to be answered through the survey or to develop hypotheses regarding possible causes or solutions to the problem(s). For example, let us assume that a manager of a supermarket is worried about dwindling store sales. On the basis of personal observations or

customer complaints, she/he may, for example, hypothesize that declining sales are due to competing stores providing better services. This hypothesis may or may not be true, and the real reasons may lie elsewhere. We need to collect and analyze the relevant data to see whether this educated guess or hypothesis is true. This is very similar to a crime investigator developing hunches regarding the person(s) who may have committed the crime. In the absence of any hunches regarding the underlying reasons for the problem, the alternative is to develop a series of questions and seek answers to those questions by collecting data. Examples of such questions, called *research questions*, are “What do supermarket shoppers care about when shopping?” “How is my store different from the competing store with regard to the things shoppers care about?” It is possible to have both hypotheses and research questions at the same time. These hypotheses and research questions essentially decide the nature and scope of a research study. Assuming that the nature of the study requires survey research, specifying the research hypotheses and/or research questions helps to identify what information is needed from the survey, or any other data collection methods, as indicated in Table 1.

For practical research that is designed to solve the problem(s) or uncertainty faced by a manager, perhaps research questions may be more useful than developing hypotheses. A research question does not require any assumption regarding the source of the problem or possible solutions to that problem. However, research questions help the researcher to be focused on answering certain questions in a given study. For this reason, it is not advisable to make the scope of any one research study too broad – do not include too many research questions in one research study.

Select the appropriate survey method. Once we know what data are actually needed to reduce the uncertainty or “solve the problem,” and assuming that we have decided to conduct a survey to collect the desired data, the next step in the research process is to decide the survey method that is best suited to collecting the desired data. There are two major methods of surveying:

Table 1 Hypotheses, research questions and data needed.

| <i>Hypotheses or Research Questions</i> | <i>Hypotheses and/or Research Questions</i> | <i>Data Required to Test Hypotheses/Answer Research Questions</i> |
|---|--|---|
| Hypothesis | Competing store provides better customer services than the services we provide | Shoppers' perception of service quality at both stores |
| Research question 1 | What do supermarket shoppers care about? | Relative importance of goods and services |
| Research question 2 | How is my store different from the competing store regarding things shoppers care about? | Shoppers' perception of goods and services at both stores |

1. Survey administered by an interviewer. Such a survey could be (i) in person or what is called a *face-to-face interview*, or (ii) over the phone with or without computer assistance.
2. Self-administered survey. This includes (i) mail surveys and (ii) online or Internet surveys.

- the online or the telephone survey would be more desirable than the other methods.
4. If there is a need for including visuals (graphics)/audio in the survey, the web-based survey and the face-to-face interview are better suited to achieving this objective than the other methods.

A comparison of these four methods is presented in SURVEY RESEARCH. Basically, we need to consider a number of factors and choose the survey method that seems to be most suitable given those factors. These are listed below:

1. The characteristics of the target population help decide which method may be most suitable. For example, the education level may determine whether a face-to-face interview is needed to explain the questions and record the responses. Similarly, if we are conducting a survey of middle-level managers, perhaps an online survey will be the most appropriate way to reach them.
2. Cost of conducting surveys varies across survey methods. The choice of method may depend upon the budget available to conduct the survey. An online survey is likely to be the least expensive whereas the face-to-face interview is the most expensive.
3. The response time of a web-based survey is faster than that of the mail survey and the face-to-face interview in that order. If there is an urgent need for the data, either

Select the type of questions. There are a variety of forms of questions from which to choose when designing a questionnaire. Every question in a survey is designed to measure what is called a *construct*. A construct is what we are trying to measure, and it could be anything – degree of satisfaction with the brand, the income of respondents, consumers' preference for certain features of a brand, the price consumers are willing to pay for a new brand, brand loyalty, consumers' reaction to the quality of service provided by a dealer, and so on. It is very important to have a clear understanding of what we are actually trying to measure. For example, let us suppose that to develop a demographic profile of consumers, we need to collect data on each consumer's income along with age, occupation, and so on. We need to define whether we need to have information regarding a respondent's income or household income? Income before tax or income after tax? Similarly, if we are trying to measure brand loyalty, we need to decide whether we are going to measure brand loyalty based on a consumer's attitude toward the brand or based on purchase behavior or both. Once we have a clear definition of what we are trying to measure, we could

choose to measure that construct or the variable by using different types of questions.

Open-ended versus closed-ended question. A closed-ended question is one for which there are a fixed number of responses. The respondent may be asked to choose only one, choose two, or choose all of the options available for the questions if applicable. For example, the number of options to choose from in the following question is fixed.

To which of the following magazines do you currently subscribe?

- () Time
- () Newsweek
- () Business Week
- () Fortune.

On the other hand, an open-ended question is one that does not provide a fixed number of options to choose from. In an open-ended question, the respondent is allowed to choose the answer in his own way rather than choosing an answer from the list provided by the researcher. Sometimes, it becomes necessary to include open-ended questions because there may be a situation where it may be difficult to know a priori the possible answers to a question. For example, if one wants to know what things the respondent likes about a city – let us say San Francisco – it is very hard to provide an exhaustive list of options. One can always restrict the answers to a few sentences or a few categories – “(Please give no more than three reasons for . . .).”

Although open-ended questions may be necessary and the detailed answers we get to such questions may be more valid and insightful than answers to a closed-ended question, one of the biggest challenges associated with such questions is the coding of answers. Open-ended questions have a tendency to invite lengthy and sometimes irrelevant responses from the

respondent. Since each respondent is answering the question in his/her own words, It will require at least two people to code the responses to ensure an unbiased coding of responses for analysis and will likely take countless hours to complete the coding. Thus it is both labor intensive and costly to code such responses. One way of avoiding open-ended questions is to conduct a pilot test of such an open-ended question. Generate the frequencies of answers obtained through the pilot test and use the most frequently mentioned categories as options in a closed-ended question in the final questionnaire. An “other” category can be added to the options to capture the rest of the infrequently mentioned answers.

Yes/No question versus multiple-point scale. Although simple to ask and seemingly easy to answer, such dichotomous options are appropriate for situations where answers are quite definite. For example, a question such as “Do you smoke cigarettes?” or “Do you have access to the Internet at home?” can be answered with a “Yes” or “No” since they are asking for the truth rather than an opinion. However, if we are interested in human psychological constructs such as attitude, perception, beliefs, and intention to buy a product, providing a simple “Yes” or “No” option is not likely to capture a range of answers. For example, for a question such as “Do you like shopping?” or “Would you be interested in buying this product if it is available at \$50?”, a “Yes” or “No” option simply forces the respondent to choose from options that may not reflect a true intention. In this type of situation, providing a range of options (a five-point scale) such as those presented below is more likely to capture the possible range of likely responses than would a simple Yes/No dichotomous response as in Annexure I.

Thus, while a Yes/No response category may be appropriate for questions related to

Annexure I

actual behavior or questions asking for facts, providing multiple options is necessary to measure constructs associated with people’s beliefs, perception, attitude, intention, and so on. Researchers have suggested different types of scales to measure such psychological constructs. They are described in detail in ITEMIZED RATING SCALES (LIKERT, SEMANTIC DIFFERENTIAL, AND STAPEL) of this encyclopedia.

Number of points on a scale. This also brings us to the issue of how many points should be used in a scale. This is an issue researchers have studied and debated. Researchers have shown that five to seven points should be enough to capture consumers’ responses to the psychological and social constructs that we tend to measure very often in business surveys using rating scales. A scale with only three points may be too few, and similarly a scale with nine points may be too many.

Availability of a neutral option. Another related issue is the question of whether to provide the midpoint (odd or even number of points on a scale). Although providing the midpoint (might/might not buy option in the previous example) allows the respondent to choose “neutral” if she/he is unsure about the issue, this also allows for an easy answer to a question if the respondent does not want to spend time thinking about how to respond. One

way of deciding whether to include the neutral option is to discuss this issue with the respondents of the pilot survey during the debriefing session.

Using multiple questions/scales to measure a construct. Sometimes, it may be necessary or advantageous to use multiple statements to measure a construct rather than asking only one question. For example, if we are interested in measuring consumers’ price sensitivity, we may ask multiple questions in different ways. This allows us to check the consistency of the answers as well as capture different aspects of *deal proneness*. Asking multiple questions to measure a construct also helps to test the reliability of those items in measuring a construct. An example of using multiple items to measure price sensitivity or deal-proneness is provided in Annexure II. Another example is provided in Annexure III.

Other essays in this book describe a number of comparative (*see* COMPARATIVE SCALING TECHNIQUE) and noncomparative scales (*see* NONCOMPARATIVE SCALING TECHNIQUE) available to measure psychological constructs. As the section on Reliability and Validity of Scales (*see* VALIDITY AND RELIABILITY) in this encyclopedia indicates, it is very important to develop scales that measure what they are supposed to measure. Testing the reliability and validity of scales is a time-consuming task. Before writing original questions for every issue

Annexure III

Please evaluate the career planning center by circling one number for each of the following items.

| | Highly Disagree | | | Highly Agree | | |
|-------------------------------|--------------------|---|---|-----------------|---|--|
| Accessible | 1 | 2 | 3 | 4 | 5 | |
| Up-to-date job information | 1 | 2 | 3 | 4 | 5 | |
| Helpful staff | 1 | 2 | 3 | 4 | 5 | |
| Useful in career planning | 1 | 2 | 3 | 4 | 5 | |
| Networking resources | 1 | 2 | 3 | 4 | 5 | |
| Courteous staff | 1 | 2 | 3 | 4 | 5 | |

that needs to be covered in the questionnaire, it is advisable to look for scales that are already developed by other researchers. For example, if we are interested in measuring consumers’ perception of quality of service provided, there are already published scales in academic journals that are reliable and valid. A good source of such a scale is Bearden, Netemeyer, and Mobley (1999).

Asking questions about demographics. Sometimes, there is a tendency to collect very detailed demographic data even if it may not be necessary for the purpose of the study. In addition, researchers may want to collect exact information (income, age, etc.) even though it may not be necessary to collect such precise information. Many respondents do not like to disclose their age, income, and other information. Asking for actual income and age is a big demotivator with respect to providing such information. However, if we ask the respondents to choose an answer from a range of answers, they tend to feel more comfortable in responding to such

questions. Examples of two alternative ways of asking questions about income are presented below:

What is your current total family income before taxes? \$_____

Please check the category that reflects the best estimate of your current total family income before taxes?

- Under \$50 000
- \$50 000–\$59 999
- \$60 000–\$69 999
- \$70 000–\$79 999
- \$80 000–\$89 999
- \$90 000–\$99 999
- \$100 000 or more

Labeling each option. Whenever possible, it is better to label each option of a rating scale rather than labeling only the end points, which is the common practice. Labels tend to

Annexure IV

How important is a “variety of choices” of fresh vegetables when deciding where to shop for vegetables?

| | | | | | | |
|-------------------|-----------------------|---|---------|---|-------------------------|----------------------|
| Very important | 1 | 2 | 3 | 4 | 5 | Not important at all |
| Very important | Somewhat important | | Neutral | | Somewhat unimportant | Not important at all |
| 1 | 2 | | 3 | | 4 | 5 |

provide clear guidance for the respondents when choosing a point on a scale, making it unnecessary for them to make their own assumptions about what the points represent. Examples of two scales, one with and one without all labels is presented in Annexure IV.

Availability of option to indicate uncertainty of answer (“don’t know” or “no opinion”). It is quite possible that given the nature of the research topic, some respondents may not have any opinion on a subject or may not know the answer to a question. This is something that can be monitored during the pilot test of the survey (described later). On the basis of the result of the pilot test, wherever needed, the researcher should offer the option of “don’t know” or “no opinion” or “undecided” so that respondents are not unnecessarily forced to choose or to give an answer.

Single versus multiple responses to a question. Sometimes, a question may require choosing only one of several options provided or choosing any combination of responses. Instructions for completing the survey should make it very clear what is expected of the respondents.

Wording the questions. The quality of information we obtain from a survey largely depends upon the quality of the questions. If the respondents do not assign the same meaning to a question that the researcher intended to assign, it does not matter whether the respondents answer that question. Although it is perhaps almost impossible to prepare a manual on how to write good questions, we can identify a number of common mistakes that are made when writing questions. They are briefly described below. The next time one sees a questionnaire, chances are that one will notice at least one of the following mistakes made in writing the questions.

Avoid leading questions. A question that also seems to suggest the answer is called a *leading question*. For example, “Do you think that outsourcing of jobs is a good idea when it leads to Americans losing their jobs?” The question is loaded with a suggested answer or tends to lead respondents to give a “right” but biased answer.

Avoid double-barrel questions. Consider

this question: “How do you like the hamburger and fries at McDonald’s?” This is one of the most common mistakes committed in writing questions. This questions has two questions embedded in it. There are four possible answers to this question: (i) I like both the hamburger and the fries; (ii) I dislike both of them; (iii) I like the hamburger but do not like their fries; and (iv) I dislike their hamburger but like the fries.

Exclude burdensome questions. Sometimes, a question may demand too much time and cognitive effort on the part of respondents. For example, a question such as “How much money do you spend on gasoline per year?” may result in wild estimates simply because the respondents do not know the answer or do not bother to spend the time to estimate the expenditure.

Avoid ambiguous options. Consider this question: “How often do you shop in a department store in a month?”

| | | |
|----------|-----------------|--------------|
| 1. Never | 2. Occasionally | 3. Sometimes |
| 4. Often | 5. Regularly | |

What is “occasionally” and what is “sometimes” may vary among respondents depending upon the reference point they use for comparison. These words do not refer to any specific numbers.

Define the construct clearly. What is your income? _____. The question does not specify individual or household income, before or after income tax, income from salary or total income from all sources, for which year, and so on.

Do not Assume. Sometimes, the researcher may have an assumption underlying a question, which is not stated in the question: “Are you in favor of improving the quality of food offered by this restaurant?” Here the assumption is that if the respondent is in favor of improving the quality of the food, she/he is also willing to pay a higher price, which may or may not be true. It also assumes that the quality of food needs improvement even though that may not be the case for some or for all respondents.

Avoid overlapping response options. Options should not overlap. Consider the following instruction and the options provided: “Please circle the number representing your age category.”

1. Less than 20
2. 20–30
3. 30–40
4. 40–50
5. Over 50.

In this question, two people aged 30 may circle two different numbers (2 and 3).

Avoid industry/profession-specific jargon/ Acronyms. Not everybody is familiar with industry (bytes for computers) or profession-specific jargon or acronyms (e.g., GPS).

Use “*Other (Please specify)* _____” sparingly as an option. Inserting “other” as an option frequently simply indicates that the researcher has not spent time thinking about possible responses. It is better to conduct a pilot test of the questionnaire and present options that capture a large majority of the respondents for a given question. Putting “other _____” is unlikely to generate responses from most of the respondents unless an important option is missing from the list of options provided.

Options need to be balanced. Unbalanced response categories is a common problem in questionnaire design. Consider the following question and the response categories: “How satisfied are you with your current computer?”

1. Very satisfied
2. Moderately satisfied
3. Unsatisfied.

In this example, there are two “satisfied” response categories and only one “unsatisfied” category. Similarly, options such as “excellent,” “good,” “fair,” and “poor” are also unbalanced. They need to be balanced to avoid creating response bias.

Options should be mutually exclusive. Consider the following question: “What is your marital status?”

1. Single
2. Currently married
3. Separated
4. Living with a partner.

There are two problems with the options provided. First, the option “Single” does not distinguish between those who have never married and those who are widowed or divorced. Second, the last option (Living with a partner) could possibly apply to the other three categories.

Include filter questions if necessary. Answers to filter questions can be used to eliminate those respondents who do not meet certain criteria so as to judge their answers to be meaningful. For example, one can include a question regarding the level of usage of a product. The researcher may decide to exclude the light users or analyze their responses separately since they may not know enough about the product to give meaningful answers.

Organization of questions. The organization of questions in a questionnaire plays a very important role in keeping the respondents motivated to complete the survey. A proper organization of questions is necessary not only to motivate the respondents, but it will also reduce the cognitive effort required to complete the survey. Dillman (2000) and other researchers have provided a number of suggestions to organize the questions in a survey.

- One should consider dividing a questionnaire into sections whereby each section represents the questions that are similar in content. For example, questions related to buying behavior may be presented in one section, whereas another section may deal with consumers’ beliefs about different aspects of a market.
- Questions should be presented in order of importance to the respondents. Many respondents do not complete surveys after answering the first few questions. For this reason, there is a tendency on the part of survey designers to put the questions in a sequence of most important to least important questions as perceived by the

researcher, hoping that at least the most important questions will be answered. Actually this strategy is not only likely to reduce the overall response rate of the survey this is also likely to lead to many incomplete surveys. To encourage the respondent to complete the survey, the questions should be arranged in the order of importance to the respondent. Once he has invested time in responding to questions that are important to him, he is likely to answer other less-important questions as well.

- First, present questions that are somewhat easier to answer. Researchers have recommended beginning with easy questions just to make the respondents feel comfortable and become interested in the survey even though those questions may not be relevant for the main purpose of the study. Once a person invests some time responding to some questions, the likelihood of completing the survey by that respondent increases significantly over that of a person who has received the survey questionnaire but has not started responding to the questions.
- Whenever possible, questions or sections of questions should be arranged in such a way that there is some kind of natural flow. For example, if we are conducting a survey about consumers' buying behavior associated with cars, a natural flow would be to first ask questions about their "knowledge" (thinking), then their "preference" (feeling), and then their "behavior" (doing).
- Demographics/classification questions should appear at the end unless any demographic questions are required to prescreen the respondents.

Physical appearance of the survey. A number of factors should be considered regarding the physical appearance of the self-administered surveys (mail and online surveys).

Font used in the questionnaire. To cram a maximum number of questions into a survey, there is a tendency to use small fonts. If the respondents have a hard time reading the questions, they will not take the extra time needed to read the questions and complete the survey

questionnaire. Fonts should be large enough so that the questions can be read with ease.

Precoding of questions. Coding of answers refers to assigning numbers to each response category so that some kind of statistical analysis can be performed on the data. If computers are used to collect the data, the precoding of closed-ended questions becomes essential. For example, if we conduct a web survey or computer-assisted telephone survey, responses to each closed-ended question are precoded so that the two tasks of collecting data and generating the data file can be done simultaneously. However, for mail surveys, options can be left without any numerical coding of those options. It is recommended that, wherever possible, the numerical codes could be included in the questionnaire itself rather than assign them after collecting the responses. This will help reduce the time it takes to code the responses later.

Provide clear instructions for each question. Do not make any assumptions regarding respondent's ability to complete the survey without clear instructions. Any given questionnaire may have different kinds of questions such as open-ended versus closed-ended, rating versus ranking questions, questions requiring a single response versus multiple responses, to name a few. Each question must be accompanied by clear instructions regarding what the respondent needs to do in order to respond to that question. For example, if one does not allow a tie in a ranking question, one needs to specify that the respondent should not use the same number to rank two objects.

Pre-testing of the questionnaire. Pretesting a questionnaire is an extremely important and absolutely necessary step in designing a quality questionnaire. The main purpose of pretesting the questionnaire is to ensure that the target respondent's interpretation of each question matches the intended meaning of the question from the viewpoint of the researcher and the respondent is able and willing to answer each question. In other words, pretesting is necessary to decrease both sampling and nonsampling errors in a survey study. Pretesting is usually done on a small sample (about 30) of respondents, representative of the population of the

study. Before finalizing the survey, it is important to test the survey on several dimensions:

1. Do the target respondents understand each question? It is quite possible that there are special words or technical language used in the questionnaire which are not in the vocabulary of respondents.
2. Are there any questions that are likely to be perceived as offensive?
3. Are the respondents able to provide the information asked in the survey (e.g., calorie intake everyday, money spent on gasoline per month, etc.)?
4. Are there certain questions that respondents tend to leave unanswered in the pilot survey? During the debriefing session with the respondents who participated in the pilot survey, ask for reasons for such behavior.
5. Are there any questions that are too long to understand?
6. Are there any questions that seem to disturb the natural flow of other questions? It is quite possible that some questions are located in inappropriate places in the questionnaire.
7. Are there questions that the respondent is hesitant to answer accurately?
8. Did the respondent understand the instructions for responding to each question?
9. Are there questions that are likely to generate socially desirable answers?

Pretesting is also important from the view point of assessing the questionnaire as a whole in terms of (i) the time it takes to complete the survey, (ii) checking to see whether additional questions are needed to cover the scope of the study, and (iii) checking the reliability and validity of new scales.

The pretesting should be done by taking a representative sample of the target population. This can be done in several ways. One way of conducting the pretest is to ask each respondent to read each question and think aloud while interpreting the meaning of the question and then answer that question. This process reveals the thought processes of the respondent and helps evaluate the quality of the questions. Another way of conducting the pretest is to involve more than one person in the administration

of the survey to a small sample of respondents. In addition to completing the survey, each respondent is asked to provide comments on different aspects of the survey during a debriefing session. A debriefing session essentially provides an opportunity for the researcher to explain the purpose of the study to the participants, to understand how they feel about the survey, and to solicit comments, if any, from them. Once the surveys are completed, the survey administrators collectively discuss the opinions of and problems encountered by the respondents and correct/improve the survey accordingly. Another way of pretesting the survey is to conduct a face-to-face interview with a small sample of respondents. To do this, after the survey is completed, discuss the survey with the participating respondents in a debriefing session.

When the survey questions are fixed after pretesting, an important step in finalizing the survey is to compare the survey with (i) the information desired listed in Table 1, which shows the list of hypotheses and research questions and (ii) the information likely to be generated from the survey to test hypotheses or answer research questions. It is quite likely that after several iterations of writing, rewriting and finalizing questions, it will be discovered that the current version of the questionnaire does not obtain some of the important information needed for the study. In that case, we need to add the missing questions. At the same time, there is very high likelihood of including questions that are not necessary. Therefore, for each question, we need to ask: "Is the question absolutely necessary given the objectives of the research?" Questions that are simply guided by the motive of "it will be really interesting to know," rather than "necessary to know given the purpose of the study," should be eliminated.

INCREASING THE RESPONSE RATE

Response rate is defined as the number of usable surveys received divided by the number of surveys actually delivered or the number of respondents actually contacted. It is generally believed that other things remaining the same, a high response rate is better than a lower response rates in order to increase the sample size and thus

reduce the sampling error. However, it must be noted that it is more important to have a sample that is representative of the target population than a high response rate. A high response rate from a biased sample simply adds to the nonsampling error to research findings. Here are a number of things a researcher can do to increase response rate.

1. Specifying the sponsor and purpose of the study
2. Sending advance notification before actual survey
3. Calling back or sending reminder
4. Offering motivation: monetary reward, summary of results, donation to charity of respondents' selection
5. Reducing the time required to complete the survey
6. Reducing the effort required to complete the survey
7. Providing assurance of maintaining respondents' privacy and confidentiality of their responses
8. Ensuring that the promise regarding incentives are fulfilled.

In conclusion, a poorly designed questionnaire is likely to affect the both quality and quantity of information collected from the survey,

ultimately increasing the total error in study findings. By following the simple guidelines presented in this article, we can improve the quality of the questionnaire significantly.

sampling techniques

Wagner A. Kamakura

It is quite rare that a marketing researcher has the luxury of studying an entire population of consumers. Most of us must resort to drawing inferences about the population from data gathered from a sample. Therefore, before gathering the data we must first select a sample of consumers that is representative of the population as a whole.

THE SAMPLING FRAME

To study a representative sample of the population, the researcher must have an accurate definition of the population from which the sample is to be drawn. While this seems rather simple and obvious, in many cases the researcher does not know precisely what the population might be. For example, if the purpose of the study is to assess the sales potential for a new energy drink, the population includes all consumers who might have a need for such a drink, making it difficult to identify members of the population *a priori*. Sometimes, a representative sample might come from a different population from the one the researcher wishes to infer about. For example, a wireless telecom might want to draw a sample from its current customers to learn how to acquire new customers who are likely to be loyal and valuable to the firm, thereby using a sample from a different population (current customers) to draw inferences about the focal population (nonusers or customers from competitors).

Because it is not always possible to identify every member of the population, the researcher must use a *sampling frame* from which to draw the representative sample. A sampling frame is a *subset of the population that the researcher believes to be representative of it*. Because only members of the population contained in the sampling frame will be chosen for the sample, it is critical that the sampling frame is representative of the population. This sampling frame can be a list of population members (such as a telephone book, or e-mail address list), but does not have to necessarily enumerate population members. For example, a city map might be used

as a sampling frame, from which the researcher draws a sample by selecting city blocks and sending interviewers to survey every third house in the block. Conversely, a sampling frame might also contain nonmembers of the population, such as a list of telephone exchanges and area codes that might include nonresidential numbers or those not in service, which can be dropped from the final sample.

SAMPLING SCHEMES

Once the researcher establishes a sampling frame, he or she must decide how members of the population will be selected from those included in the sampling frame. There are two basic sampling schemes that are discussed in more detail elsewhere: *probability* (see PROBABILITY SAMPLING) and *nonprobability* (see NONPROBABILITY SAMPLING) sampling schemes. In the probability sampling scheme, each member of the population contained in the sampling frame has a known (but not necessarily equal) probability of being included in the sample. If the sampling frame is representative, random sampling is expected to produce a representative sample of the population. In the nonprobability sampling scheme, sample selection is not left to chance, but is based on some criteria defining whether members of the sampling frame are of interest for the study at hand.

Given that the researcher's goal is to draw inferences about the population from the sample, a major concern is the discrepancy between the measurements observed in the sample and their respective population values, which are unobservable. *Systematic variation* or *sampling bias* occurs when subjects selected for a sample over-/underrepresent the population features under study. For example, a sample of telephone interviews reaching people at home during the evening is likely to produce a biased sample for a life-style survey, because it will underrepresent consumers enjoying life away from home. Systematic variation or sampling bias may occur in different forms in a marketing research study:

- *Nonresponse bias*: In a typical survey study, low response rates may render the effective sample of respondents nonrandom, even when a random sampling scheme is used

2 sampling techniques

to draw the original sample. Low response rates may also render the effective sample nonrepresentative, when the profile of respondents deviates from nonrespondents. This sample bias is often assessed by attempting to contact a portion of the unresponsive sample elements and comparing respondents and nonrespondents on the main variables being measured.

- *Coverage bias*: When certain types of population members do not appear in the sample frame, the observed sample values deviate from the population owing to differences between covered and noncovered units. This type of bias is a concern in certain web surveys when the target population is not fully covered by this particular medium.
- *Selection bias*: When some members of the population have a higher/lower probability of sample selection than planned by the researcher. For example, random-digit dialing is likely to produce selection bias because some households have multiple phone numbers making them more likely to be sampled than households with only one phone number.

When sampling bias cannot be avoided, data collected from the sample must be weighted to correctly represent the population. For example, a sample collected by intercepting shoppers at a shopping center is likely to overrepresent frequent and slow (those who linger longer) visitors to the center. The researcher may reduce this selection bias by weighing each sampled respondent inversely to the number of trips in the past six months and minutes spent at the center prior to the interview.

Random variation or error occurs due to chance, rather than human biases, and can be assessed statistically when the sample is drawn randomly (see UNIVARIATE TECHNIQUES). Because selection of sample elements is nonrandom, nonprobability sampling does not allow for the assessment of sampling errors.

Sampling schemes also differ on whether sample elements are collected with replacement (a member of the sampling frame may be sampled more than once within the same study) or without replacement; most marketing research studies use samples without replacement.

Sample biases due to nonresponse can also be mitigated by weighting respondents in proportion to their over-/underrepresentation in the final sample relative to the population profile.

SAMPLING METHODS

A variety of sampling methods are available to the marketing researcher, following the probability and nonprobability sampling schemes discussed above. The choice of one of these methods depends on cost considerations, the type of sampling frame used to draw the sample, the availability of additional information about each member of the sampling frame, and whether it is important to assess sampling error. For more details on sampling methods, see Govindarajulu (1999) and/or Cochran (1977).

Convenience or opportunity sampling. This is probably the most common form of sampling method used in commercial marketing research. It involves sampling consumers who are members of the target population and happen to be more easily available to the researcher. The main reason for the popularity of this nonprobability sampling method is cost. Another common justification for using convenience samples is that response rates to marketing research are often low, thereby making the effective samples obtained from probability sampling methods (discussed below) as representative/non-representative as those obtained with this simple and less expensive method.

One form of convenience sampling particularly useful to sample hard-to-find populations is *snowball sampling*, where sampled subjects are asked to help recruit additional members to the sample. Another form of convenience sampling is *judgment sampling*, in which the researcher selects the sample based on judgment. For example, a researcher may elect to run a test market in a few “representative” metropolitan areas, even though the population of consumers includes all cities.

Because bias and representativeness are major concerns for this type of sampling, the researcher must ascertain that the sample profile does not depart considerably from the population on relevant aspects to the study at hand.

Simple random sampling. In a simple random sample, members of the sampling frame are randomly drawn for the sample with the same probability, in an attempt to minimize sampling bias and obtain a representative sample (*see* PROBABILITY SAMPLING). However, simple random drawing may result in the over- or underrepresentation of small segments of the population. For example, suppose that ethnicity is a critical aspect in a particular study and Asians represent 2% of the population. A sample of 100 members randomly drawn from the population may contain no Asian or 5 Asians, leading to no representation or overrepresentation of this particular segment. Simple random sampling might also be impractical in some cases, because it requires that the researcher assigns equal selection probability to each member of the sampling frame.

Systematic random sampling. A more convenient way of drawing a random sample from a sampling frame is by systematic random sampling. Suppose the sampling frame is a list containing 6000 members and the researcher needs a random sample of 200. The first step in systematic random sampling is to define the sampling interval, which, in this example, is 30 ($6000/200$). The second step is to draw a number randomly from the sampling interval (between 1 and 30 in this example), which defines the first sample element. For example, suppose the random number was 16. Then, the 16th member listed in the sampling frame will be the first selected member for the random sample. From this random starting point, the researcher selects every 30th member listed in the sampling frame, until reaching the end of the list. Because the first member was chosen at random, the resulting sample is a simple random sample.

If the sampling frame is sorted according to some consumer characteristic of interest (e.g., ethnicity), the systematic random sampling procedure described above will ensure that each segment (e.g., Asians, Hispanics, etc.) is represented in the same proportion in the sample as it is in the sampling frame, leading to a proportionate stratified random sample, as described next.

Stratified random sampling. In cases where the population is categorized into relevant segments or *strata* and the sampling frame contains information about this segmentation, a stratified random sample can be drawn to ensure that each *stratum* or segment is represented in the same proportion within the sample as in the sampling frame. The first step is to segregate the sampling frame into strata of interest (e.g., ethnic groups). Each stratum is then treated as an independent subpopulation, and a simple random sample drawn from each. Aside from ensuring that each stratum is properly represented in the sample, this stratified sampling produces more efficient statistical estimates, if each stratum is more homogeneous relative to the differences across strata, in terms of the construct being measured.

Since each stratum is treated as an independent subpopulation, different random sampling methods may be applied to each. A common variation of stratified random sampling is *nonproportionate stratified sampling*, where the relative sizes of the strata in the sample depend on their heterogeneity, so that more consumers are sampled within heterogeneous strata than in more homogeneous ones, to improve overall statistical efficiency.

Another form of nonproportionate stratified random sampling is *choice-based sampling*, where the sample is stratified on the choice outcome and a sample is taken from each strata so that the less frequently observed strata is overrepresented in the sample. A statistical model is then built on this biased sample, and the effects of predictor variables on choice can be estimated with more precision with this choice-based sample, compared to a random sample. This sample design is often used to study rare events, and the final results are adjusted to correct for the oversampling of the rare events.

Cluster random sampling. When the sampling frame is naturally organized into “minipopulations,” each with a profile that represents the population, a cost-effective random sample can be drawn using cluster random sampling. For example, a textbook publisher interested in interviewing students of secondary schools may consider each secondary school as a “minipopulation” and draw a cluster sample in two

4 sampling techniques

or more stages. The first stage would be to draw a random sample of secondary schools from a sampling frame. In a second stage, the researcher could draw a sample of classrooms in each of the sampled schools. A final sample would then be collected in a third stage, by randomly drawing a sample of students in each of the sampled classrooms. Cluster random sampling typically results in lower costs, but can increase the sampling error relative to simple random sampling, depending on how the clusters differ from each other, compared to within-cluster variation. In contrast to stratified random sampling, in cluster sampling one wants high within-cluster variance, relative to between-cluster variance. In other words, in cluster sampling one wants each cluster to be as representative of the population as possible. Cluster sampling is used to draw random samples for door-to-door personal interviews by first drawing a random sample of city blocks and then drawing random samples of houses within each of the sampled blocks. Another example of cluster sampling can be found in random-digit dialling for phone surveys, where one first draws a random sample of exchange/area-code combinations, and then draws random suffixes within each of the chosen exchange/area-code combinations.

Quota sampling. This nonprobability sampling method is similar to stratified random sampling. The first step, of classifying the sampling frame into strata, is the same, but instead of drawing members from each stratum or segment at

random, judgment is used for this selection in quota sampling. This type of sampling is common in intercept surveys, where the interviewer is placed at some location and asked to sample a given quota of consumers fitting a specific profile (e.g., 200 female consumers between 20 and 30 years of age). Because the selection of respondents fitting the specified profile is left to the interviewer, the sample may be biased by the interviewer's decision process; for example, the interviewer may choose to interview those who appear more approachable or friendly.

Once the sampling frame has been defined and the sampling method chosen, the next step is to decide for the sample size, which is the subject of another article (*see* STATISTICAL APPROACHES TO DETERMINING SAMPLE SIZES) .

statistical approaches to determining sample sizes

Wagner A. Kamakura

The main reason for a researcher to draw a random sample is to make statistical inferences about the population, on the basis of a more affordable and more manageable set of observations than canvassing the entire population (*see* SAMPLING TECHNIQUES). The main question then is how large the sample should be to allow for this inference regarding the population. All else being equal, a larger sample will lead to more precise estimates about the population. Therefore, before determining the sample size, the researcher must first decide how much precision is required in the inference about the population.

SAMPLE SIZE TO ESTIMATE THE POPULATION MEAN OR PROPORTION

If the purpose of the study is to estimate the population mean (or proportion) on a continuous (or binary) variable (*see* UNIVARIATE TECHNIQUES), the researcher must specify the maximum accepted error and the desired confidence level. In other words, the researcher wants the population mean (or proportion) to be within *ERROR* units from the sample result, with a confidence level *CL* (typically expressed in a proportion).

If a large enough sample is collected, the distribution of the sample mean \bar{x} (or proportion p) approaches a normal distribution centered around the unknown population mean (or proportion) and a variance equal to the population variance σ^2 divided by the sample size n . In other terms, the difference between the sample and population means (or proportions), which we defined as *ERROR*, is normally distributed with zero mean and a standard deviation equal to $\sigma_{\bar{x}} = \sigma/\sqrt{n}$ (or $\sigma_p = \sigma/\sqrt{n}$), where σ^2 is the population variance and n is the sample size.

Therefore, the researcher wants a sample size such that the probability of the population estimate falling within *ERROR* units from

the sample result is *CL*, or

$$\begin{aligned} & \Pr\{\bar{x} - \text{ERROR} \leq \mu \leq \bar{x} + \text{ERROR}\} \\ &= CL = \Phi\left\{\frac{\text{ERROR}\sqrt{n}}{\sigma}\right\} \end{aligned} \quad (1)$$

$$\begin{aligned} & \Pr\{p - \text{ERROR} \leq \pi \leq p + \text{ERROR}\} \\ &= CL = \Phi\left\{\frac{\text{ERROR}\sqrt{n}}{\sigma}\right\} \end{aligned} \quad (2)$$

Given that our goal is to determine the sample size needed to achieve a precision of *ERROR* units at a confidence level of *CL*, we solve for N , obtaining

$$n = \frac{z^2 \sigma^2}{\text{ERROR}^2} \quad (3)$$

where

$$z = \Phi^{-1}\{CL\} \quad (4)$$

A commonly used confidence level is 0.95 (leading to the 95% confidence interval), with a corresponding $z = 1.96$, which is often rounded up to 2.

The sample-size formula above is inconvenient because it uses knowledge about the population variance before the sample is collected. If the sample is being collected to estimate a population proportion, the largest possible population variance is 0.25 and therefore, the largest needed sample size would be $n = \frac{(0.25)z^2}{\text{ERROR}^2}$, which for $CL = 0.95$ simplifies to $n = \frac{z^2}{\text{ERROR}^2}$, a simple formula commonly used to define the sample size for opinion polls and other surveys. For example, if the survey is to produce estimates with a margin of error of 5% and confidence level of 95%, the required sample would be 400 ($1/0.0025$).

If the purpose of the sample is to infer the population mean, a rough estimate of the population variance can be obtained by approximating the standard deviation σ as one-sixth of the likely range of the focal variable in the population. A better approach is to collect the sample sequentially, starting with a reasonably small sample, using the variance in this sample as a substitute for the population variance in the sample-size formula, drawing more members to the sample, and repeating the process until the final required sample is collected.

2 statistical approaches to determining sample sizes

SAMPLE SIZE FOR STRATIFIED SAMPLING

Proportionate stratified sampling. To draw a proportionate stratified sample, the required sample size for the smallest strata in the population is determined. For example, if the sample is being stratified by marital status and there are fewer widows in the population, the researcher starts by setting the sample size for widows. The standard formulas for simple random sampling are used to calculate the sample size in the smallest stratum for the desired error level and level of confidence for this stratum. Next, the total sample size is calculated by dividing the sample size of the smallest stratum by its proportion in the population. For example, if it is concluded that the researcher needs to sample 100 widows and they represent 5% of the population, then the total sample size is 2000 ($100/0.05$). Finally, the sample size is calculated in each of the other strata needed to achieve the same ratio in the sample as in the population.

Nonproportionate stratified sampling. In this case, the researcher wants to find the relative sizes of each stratum that provide the most precision, given a fixed sample size. The solution to this problem is the optimal allocation rule where the relative size of each strata in the sample is directly proportional to its size and variance in the population:

$$n_i = \frac{n(N_i\sigma_i)}{\sum_{i'} N_{i'}\sigma_{i'}} \quad (5)$$

where n is the total sample size; N_i is the size of stratum i in the population; σ_i is the population standard deviation within stratum i .

SAMPLE SIZE FOR HYPOTHESIS TESTS

A common problem facing marketing researchers is to draw a sample to perform a hypothesis test (see HYPOTHESIS TESTING RELATED TO DIFFERENCES – PARAMETRIC TESTS) with a known statistical power, given a predetermined Type I error α . For example, the

researcher wants to collect data on a continuous variable from a random sample to test the following null hypothesis about the population

$$H_0 : \mu = \mu_0 \quad (6)$$

against an alternative hypothesis

$$H_a : \mu = \mu_a \quad (7)$$

The researcher wishes to reject the null hypothesis H_0 with a probability of at least $1 - \beta$ when the alternative H_a is true. The probability $(1 - \beta)$ is the power of the test, or the ability to reject the null hypothesis when it is false. However, the researcher also wants to control the error in the test, so that it rejects H_0 when it is true with a predetermined probability α (known as the *Type I error*).

Given the desired Type I error α , the researcher's decision rule is to reject the null hypothesis H_0 when $\bar{x} \geq z_\alpha \frac{\sigma}{\sqrt{n}} + \mu_0$, where $z_\alpha = \Phi^{-1}\{1 - \alpha\}$ and $\Phi^{-1}\{\}$ is the inverse standard normal cumulative density function.

However, the researcher also wants a power of $1 - \beta$, thereby requiring that

$$\bar{x} \geq z_\beta \frac{\sigma}{\sqrt{n}} + \mu_a \quad (8)$$

where

$$z_\beta = \Phi^{-1}\{1 - \beta\} \quad (9)$$

Combining the Type I and power conditions, one obtains the same size

$$n = \sigma^2 \left(\frac{z_\alpha + z_\beta}{\mu_a - \mu_0} \right)^2 \quad (10)$$

survey research

Jagdish Agrawal

Survey research refers to the method of collecting data by means of a set of questions commonly known as a *questionnaire*. The questionnaire can be administered through personal interviews (face-to-face interviews) or through mail, telephone, fax, or *via* online (electronic) surveys. Although there are other well-known methods of collecting data (such as experiment and observation), conducting surveys by means of a questionnaire is perhaps the most popular means of collecting data for academic, industry (private), and government research. The availability of the Internet as a new mode of surveying has further made the survey method of collecting data more popular than ever before. This section describes the four most popular methods of conducting surveys: personal (face-to-face) including mall-intercept interview, telephone interview, mail survey, and online (electronic) survey. Table 1 presents a comparative evaluation of these four methods.

PERSONAL (FACE-TO-FACE) INTERVIEW

Collecting data through a personal interview is the oldest method of conducting a survey. The US government still relies on personal interviews for collecting census data every 10 years. The personal interview involves face-to-face interaction between an interviewer and an interviewee. The interview may involve a single respondent or multiple respondents. For example, an interviewer may be interested in knowing the roles different people in a household play while buying a new house or a new car. The interview may take place at the home of the interviewee. Sometimes, the interviewer may simply intercept potential interviewees in shopping centers and conduct the interviews on the spot or request that they go to a research facility designed for such interviews. This practice is commonly known as *mall-intercept interviews*. Although personal interviews are usually conducted using the paper-and-pencil method of asking questions and recording responses, the computer-assisted personal interview (CAPI) method is gaining popularity. In the CAPI

method, the respondent views the questions on a computer terminal and types the responses. Data collected through personal interviews are prone to data-coding and typing errors. An added advantage of computer-assisted interviewing is that software can perform internal checks for a range of valid answers, choice of a single versus multiple responses, skipping of certain questions depending upon the answer to previous questions, and so on. The system also enables the simultaneous creation of a data file of responses while interviews are being conducted.

In many countries, where the postal system is not very reliable and where a modern means of communication (such as the telephone and Internet) are not yet widely available, the personal interview is still the dominant means of collecting survey data. Even if other means of conducting surveys were as widely available as in the United States, there are times when the personal interview is still the most suitable means of collecting data. For example, the personal interview becomes somewhat of a necessity if the researcher wants to show an object (such as a product or advertisement or any other promotional material) and get the respondent's reaction to specific questions regarding such objects. For this reason, mall-intercept interviews are very popular. Personal interviews are also suitable for open-ended questions that may require lengthy answers and/or require further probing of answers. Once a rapport is established between the interviewer and the respondent, the length of the survey is less problematic in the personal interview than in other methods. Because of the presence of the interviewer, personal interviews also allow the flexibility of asking questions in different formats. The interviewer can help clarify the questions and response options.

In spite of a number of distinguishing advantages of personal interviews over other methods of collecting data, the personal interview is the costliest method of collecting survey data. It requires hiring well-trained interviewers. Not only do the interviewers have to persuade some people to participate in the survey, they also have to administer the survey and record responses without any personal bias. Whether done at a residence or at shopping mall, getting the cooperation of people to participate in a personal interview is a daunting task. Unlike

Table 1 Comparisons of methods of conducting surveys on a few major dimensions.

| <i>Characteristics</i> | <i>Mail</i> | <i>Face-to-Face</i> | <i>Web-Based</i> | <i>Telephone</i> |
|---|-------------|---------------------|------------------|------------------|
| Response time | Long | Longest | Shortest | Short |
| Costs | Low | Highest | Lowest | Moderate |
| Data processing required | Yes | Yes | No | Yes |
| Ability to show stimuli | Limited | Very high | Moderate | None |
| Length of survey | Long | Longest | Short | Short |
| Ability to handle complex questions | Limited | Highest | High | Lowest |
| Response rate | Moderate | High | Low | Moderate |
| Coverage of general population | Very high | High | Limited | Very high |
| Ability to handle sensitive information | Moderate | Limited | Limited | Moderate |
| Availability of data in real time | No | No | Yes | No |
| Easy to follow up | Easy | Most difficult | Easiest | Easy |
| Ease of doing it operationally | Moderate | Difficult | Easy | Easiest |
| Ability to probe responses | Limited | High | Limited | High |
| Use of open-ended questions | Limited | Ideal | Limited | Moderate |

The evaluation of methods is based on the assumption that data collection is done in-house rather than by outside vendors.

other methods, including the telephone survey, where the respondents do not see the surveyors, face-to-face interviews are also susceptible to influence due to the way the interviewer asks the questions, his/her personality, and demographic characteristics. Interviewers might also introduce biases in recording responses. For example, the interviewer could record the responses to open-ended questions as per his/her interpretation of the responses given by the interviewee. One of the common problems in the face-to-face interview is that many interviewers tend to use their own language when asking questions rather than adhering to the language specified in the survey questionnaire. Obviously, conducting personal interviews requires the need for very well-trained interviewers who can not only persuade respondents to participate in interviews but also ask questions and record answers in a very objective manner.

Shopping malls are convenient locations to find people to conduct face-to-face interviews with. The mall-intercept personal interview essentially involves intercepting someone in a shopping mall to conduct a personal interview. The interview may take place right where the person is intercepted or in a research facility located inside the mall. Those who participate are rewarded monetarily or with coupons.

Apart from being able to locate people for interviews, mall-intercept interviews provide a very good opportunity to collect data on concept and taste tests. Unlike the face-to-face interview conducted at someone's residence, mall intercepts also allow for conducting marketing experiments at research facilities inside malls.

There are a number of issues related to sampling in mall-intercept surveys. First, not everybody in the target population is likely to visit malls or do shopping at malls. In addition, there is also a tendency on the part of solicitors or interviewers to approach only those who they think are likely to agree to be interviewed. This obviously creates further bias in sampling. To make sampling somewhat meaningful, it is suggested that interviews be conducted at different malls and on different days and times. It is also important to randomize the sample selection by approaching every n th person passing by a particular location rather than using judgments of solicitors/interviewers. The researcher can also use quota sampling to ensure that respondents of different backgrounds are represented in the sample so as to reflect population characteristics.

A low response rate compared to face-to-face interviews at residences is believed to be another challenge related to mall-intercept interviews.

Research by Hornik and Ellis (1988) shows that solicitors could use a "gaze and touch" technique to generate compliance when intercepting individuals and requesting an interview time. Furthermore, female solicitors employing this tactic tend to further increase the response rate.

TELEPHONE SURVEY

Conducting surveys on the telephone is one of the most popular methods of conducting surveys in the United States. Most of us, no doubt, have been interrupted by a phone call during dinner, not realizing that the person at the other end is interested in asking a few questions about some topic that may or may not be interesting to us. This method is becoming even more popular in other countries where per capita landlines are very limited, but owing to the very low cost of using cellular phones, this is the fastest way of reaching a large number of people. Telephone surveys can be conducted with or without the help of a computer. In the traditional method, the interviewer asks the questions and records the responses on the questionnaire. Once the surveys are completed, the responses are entered into the computer for analysis. However, computer-aided telephonic interview (CATI) allows the interviewer to record the responses directly into the computer, thus reducing the time required for data coding and creation of a database. Not only does CATI offer this significant advantage over the traditional method, the computer can also direct the interviewer to the appropriate follow-up question depending upon the responses to previous questions. With or without computer assistance, the telephone survey allows interaction between the interviewer and interviewee so that the interviewer can clarify a question and address any concerns. However, since the interaction is indirect, unlike the face-to-face interview, the problems associated with interviewer influence are less pronounced in the telephone interview.

The only things required to conduct a telephone survey are a list of telephone numbers and a questionnaire with a list of questions to be asked. Perhaps this is the easiest way of reaching respondents. The interviewer can use telephone directories to obtain phone numbers

or purchase a list of telephone numbers of households that meet certain demographic or psychographic criteria. Because many households have an unlisted number, one way of reaching households with and without listed numbers is to engage in random digit dialing. After selecting the area codes and exchange codes of the target population, the last four digits of the telephone numbers can be randomly generated with the help of the computer. Although it solves the problem of not reaching unlisted numbers, this method also generates numbers that are not assigned or those that belong to a nontarget group (businesses, universities, or government offices rather than residences). The response time to the telephone survey is also minimal compared to the mail survey. By using many people to conduct the surveys, it is easy to collect data from several hundred people within a few days or a week at a much lower cost than mail surveys. This benefit, of course, comes at a cost. Telephone surveys are not suitable for lengthy surveys. Because of the misuse of this method (especially by telemarketers who try to promote products under the pretext of conducting surveys), people are becoming less receptive to responding to phone calls asking to conduct a survey. Whether the telephone survey takes place after a cold call or during a prearranged time, it is important to keep the survey to a reasonable length. Telephone surveys are also suitable for simple-design survey questions. Since the respondent has to remember the question, short questions and fewer options are essential for collecting quality data using the telephone survey.

The advent of cellular phones has provided new opportunities for collecting data through telephone surveys, especially in those countries where access to telephones is very limited. Owing to technological advances linking the Internet and cellular phones via Voice over Internet Protocol, the cellular phone could become a completely unique medium of conducting surveys.

Although the random sampling method allows the researcher to generate estimates that are representative of the population within a certain confidence interval, there is no guarantee that everybody selected or approached using the random sampling method will cooperate by

responding to the survey. Depending upon the method of survey used, the nonresponse rate may even exceed 50% of the original sample. It is reported in the literature that response rate, in general, and for telephone surveys, in particular, are declining. The low response rate could be due to both inability to contact individuals by phone (not at home, wrong number, disconnected number, refusal to answer the phone) and refusals to participate in the survey by those who are contacted.

If the response rate is very low, it may introduce the error due to nonresponse bias because of the difference between the responses of those who responded to the survey and those who were not contacted or refused to participate. As a result, literature on research methodology suggests increasing the response rate, which can be achieved at an additional cost. However, analysis of results of the published studies by Groves (2006) show that there is not any necessary relationship between nonresponse rate and nonresponse bias, although a high response rate can help reduce the potential risk of bias. Groves (2006, p. 669) suggests identifying and collecting data on auxiliary variables that are: "... simultaneously correlated with response propensity and the key survey variables." This will allow the need to make necessary postsurvey adjustments in responses collected through the probability sampling method. A number of actions, which do not involve a significant increase in the cost of collecting additional data, can be taken to increase response rate: Prenotification of survey, call back by redialing at different times and days, and pilot test of questions to identify the question(s) that discourage participation. Accessing participants through random digit dialing can also help ensure a representative sample to allow for postsurvey adjustments (*see SAMPLING TECHNIQUES*).

MAIL (POSTAL) SURVEYS

Similar to telephone surveys, mail surveys are also very popular methods of collecting survey data. Mail surveys are the least intrusive of all the survey methods. They are completely self-administered by the respondent without any kind of assistance from the researcher. As a matter of fact, e-mail surveys are essentially

electronic versions of mail surveys – of course, with some distinct features of their own. In mail surveys, printed questionnaires are mailed out to a sample of addresses of the target population. Depending upon the purpose of the study and the target population, addresses can be obtained from Associations (of growers, manufacturers, distributors, etc.) and telephone directories, or they can be purchased from research organizations (e.g., Dun & Bradstreet). Although there is no guarantee of who actually completes the survey, we can specify the target group in terms of its business characteristics such as type of industry, size in terms of annual sales and number of employees, and other features, to generate the sample of addresses according to the research need. Similarly, addresses are available that match certain demographics and psychographics. A common problem that arises from buying addresses from a third party is that many of the addresses tend to be outdated, resulting in a large portion of surveys being returned undelivered. This fact needs to be considered when deciding how many surveys to mail out.

Given the fact that mailed surveys are self-administered, it is very important to mail the questionnaire accompanied by a very well-articulated cover letter. At a minimum, a cover letter should identify the sponsor of the study, the purpose of the study, explain how the confidentiality of the responses and privacy of the respondents will be maintained, and include a request to return the completed survey by a certain date. Previous research has shown that prenotification helps to increase the response rate. To reduce the chances of recipients of a survey simply discarding it without paying any attention to it, a postcard or a letter prenotifying respondents about the forthcoming survey helps to build expectation about the survey. This increases the likelihood of the recipients of the survey paying at least some attention to it before deciding whether to complete the survey.

In addition to the cover letter, the surveyor needs to ensure that the respondent does not have to bear any cost of returning the completed survey. The surveyor may also choose to include an incentive, if any (cash, coupons, etc.), or a promise of incentive (e.g., donations to a charity for every completed survey). A promise to send a short summary of the research findings is

a good incentive in the case of respondents from businesses. Research on the response rate of mail surveys shows that multiple contacts made to encourage respondents to complete a survey, salience of topics covered in the survey, incentives provided to motivate response, and organizations that sponsor research have an influence on the response rate (Dillman, 2000).

Because mail surveys are self-administered, designing a mail survey is a challenge. Once the questionnaire is mailed out, the researcher has very little opportunity to interact with the respondents. Usually, the cover letter contains an 800 number so that respondent can call if she/he has any questions or concerns regarding the survey. In general, everything in the questionnaire has to be self-explanatory so that it is easy to understand each question and the response categories. In addition, it has been reported that not only the words used in questions but also the visual design of the questions have a significant impact on the response behavior in self-administered questionnaires (Christian and Dillman, 2004). The visual design may relate to the listing of items from which to choose, the labeling of all response categories on multiple-point scales, and so on. However, unlike a telephone survey, the mail survey allows the incorporation of complex questions such as the ranking of objects or the distribution of fixed points across alternatives.

Since the respondent has complete control of the questionnaire and does not have to complete the survey in one sitting, the mail survey is perhaps the best suited for addressing multiple research questions in one study. In interviewer-administered surveys (such as the face-to-face and telephone interview), surveys are completed during the first interaction. Similarly, in the case of the online survey, even though the respondent can save a partially completed survey, she/he has to sit in front of a computer to complete the survey. Therefore, it does not give the same freedom to the respondent as does a mail survey. Because it allows the respondent to take time to complete the survey, other things remaining the same, the quality of data collected through a mail survey is likely to be better. Since the respondent can complete the survey in privacy, the mail survey

is also perhaps the most suitable for research on sensitive issues.

There are a large number of studies that have examined the impact of monetary and nonmonetary incentives on the mail-survey response rate. A number of researchers have also performed integrative reviews of these studies to derive conclusions that are generalizable across studies (Groves, 2006; Groves and Peytcheva, 2008). Some of the important findings of the studies dealing with this issue, and having very practical implications, are as follows:

1. Response rates to mail surveys in general can be increased through incentives.
2. Monetary incentives tend to produce a larger effect than nonmonetary incentives.
3. The nature of the relationship between the amount of monetary incentives and the response rate is not well established. Results are mixed regarding the relationship being linear or characterized by diminishing returns.
4. It is better to include incentives with the initial mailing of the survey rather than making a promise of rewards contingent upon return of the survey.

In summary, there is no doubt that incentives work to increase response rate, and a prepaid cash reward included in the first mailing of surveys produces the best results.

A natural question is: Do the incentives create any kind of response bias? Is it likely that respondents who are attracted to respond owing to incentives respond differently than those who would respond without any incentives? Although this issue has not been examined as extensively as the impact on response rate, the findings of a limited number of studies addressing this issue are encouraging. Results suggest that there is no evidence of any systematic bias in responses as a result of incentives to encourage higher response rates (Mizes, Fleece, and Roos, 1984).

ONLINE (ELECTRONIC) SURVEYS

The worldwide web or the Internet is the latest addition to the types of different modes for conducting surveys. Although the coverage of the general population by the Internet is yet to

match that of the telephone and regular mail, the number of people using the Internet for one reason or another has been rapidly increasing. It is already a very effective means of surveying special interest groups of people living anywhere in the world.

There are two major modes of doing surveys online. The first is the e-mail survey, where either the questions are embedded in the e-mail itself or a separate file containing the questionnaire is attached to the e-mail. E-mails are sent out with or without seeking prior approval of the prospective respondents. The second mode is the web-based survey in which a list of respondents are sent the link to the survey via an e-mail requesting that they participate in the survey by clicking on the web address. This is the easiest way, for example, of conducting a survey of employees who may be located worldwide. E-mail addresses of different target groups of people are available from commercial companies. The survey may reside in the server operated by the researcher or by someone else (such as commercial companies, e.g., Survey-Monkey.com, Zoomerang.com). These companies, and many others, not only provide software to create/design surveys but also provide support services to take care of the complete task of the administration of the surveys, data storage, and generation of basic statistics from the responses. The survey link can also be posted on a private web site where visitors are encouraged to participate in the survey. In this section, the focus is on the web survey rather than the e-mail survey. The web survey is not simply an alternate way of delivering and receiving a mail survey. Because of the technology employed in designing and transferring surveys, it offers many distinct advantages over other methods. Depending upon the target group of respondents, the web survey is perhaps the fastest way of getting survey responses back at a very low cost.

Even though it is similar to the mail survey in that the web survey is self-administered, Internet technology allows the incorporation of certain design features in the questionnaire that are not feasible in other modes. For example, software used to design online surveys allows automatic skipping of questions depending upon the response chosen to previous questions or does not allow the skipping of a question. It can also

restrict responses to valid categories (allowing single vs. multiple responses, not allowing ties in ranking, etc.). Because of these features, the researcher does not have to spend additional time checking the data for errors. Randomizing choices to reduce order bias can also be incorporated into the survey. The drop-down menu feature allows listing a large number of options without giving the impression of a lengthy survey. Online surveys also incorporate images, color, animation, and sound. These are just some of the features that make online surveys a very attractive mode of conducting surveys. There are a large number of online companies that provide survey design services and will conduct the survey and report results of the survey at a very low cost. It is not necessary to be technologically savvy to design a simple online survey.

Another great advantage of conducting a survey online is that the results can be obtained in real time. As the respondents complete the survey, responses are recorded directly into the database, ready for analysis. The researcher still has to decide how to handle responses to open-ended questions; but otherwise, this mode reduces a great deal of effort that is required to code responses and create data files. This advantage comes with few additional costs. As a matter of fact, the online survey method is the least expensive method of surveying respondents worldwide. Analysis of findings of previous research shows that the response rate of online surveys is influenced very significantly by the salience of the subject matter. Interestingly, survey length does not seem to have a significant negative impact (Cook, Heath, and Thompson, 2000).

Issues of privacy and confidentiality are the major concerns associated with online surveys – much more so than the other methods. The fact that someone unfamiliar obtained your e-mail address and sent you an unsolicited request to complete a survey is enough to raise concerns. Unlike other methods, it is very easy and costless to send multiple reminders to complete the survey. Sometimes, reminders are sent even to those who have already completed the survey. In addition, there is also the fear of the respondent's identity being revealed or not kept confidential. Researchers in this area have provided a number

of guidelines to address this issue (Andrews, Nonnecke, and Preece, 2003). For example, it is suggested that the cover letter invitation to complete the survey should be sent separately with the option to "opt in" to the actual survey, and that there should be a guarantee of protecting personal data. This process not only respects a respondent's privacy but also helps to increase the response rate.

CONCLUSION

As indicated by Table 1, which compares different methods on a number of dimensions, each method has its own pros and cons. Each method is more or less suitable for certain tasks. As a result, these different methods of conducting surveys are not substitutes for one another, but they are at best complementary. Some researchers have suggested using multiple methods to collect data; although using multiple methods is not always practical. What it essentially means is that we have to select the survey method very carefully based on the purpose of the study and the relative importance of the advantages and disadvantages of different methods. No matter what method is chosen to conduct the survey, it is very important to respect the privacy of respondents and honor the confidentiality of their responses.

analysis of variance and covariance

Sangkil Moon

Laura, a marketing researcher, is interested in examining how different MP3 players influence consumers' satisfaction in music listening. Her primary interest lies in whether there is any difference in music-listeners' satisfaction when they use different MP3 player brands. She chooses three well-known top brands to be compared (categorical independent variable with three categories) – Apple's iPod, SanDisk, and Microsoft's Zune. She also invites 300 typical consumers (overall sample size) of various demographic characteristics chosen at random (random sampling). In an artificial laboratory setting (*see* EXPERIMENTAL DESIGN), she randomly assigns each of the 300 consumers to one of three groups consisting of 100 subjects (category sample size). Now, she gives each consumer group one of the three MP3 player brands. Once she exposes the subjects to the same music for the next 30 minutes, she asks them to evaluate their satisfaction about the quality of the music they just listened to on a 10-point scale (metric-dependent variable). When Laura conducts this experiment and collects data, she can determine whether MP3 player brands influence music listening quality by using a statistical methodology named *analysis of variance* (ANOVA).

Similarly, another marketing researcher, James, exposes three groups of subjects to three distinct advertising messages (categorical independent variable with three categories) and, subsequently, asks them to rate the appeal of the advertisements on a 7-point scale (metric-dependent variable). James randomly assigns the subjects to one of the three groups, and obtains three sample means to compare. To analyze these data, he also uses ANOVA to determine whether the entire set of sample means suggests that the samples were drawn from the same general population (Hair *et al.*, 1995).

Thus, ANOVA is used to determine the probability that differences in means across multiple categories are due solely to sampling error. Quite often, data for ANOVA are effectively collected in artificial laboratory settings through careful and systematic experimental design as implied

in the two examples above. This article is aimed at providing some basics of ANOVA for MBA and undergraduate students, particularly those interested in marketing research.

This article is organized in the following order. First, ANOVA is introduced with the experimental design. Then, several types of ANOVA are discussed one by one such as one-way ANOVA, *N*-way ANOVA, analysis of covariance (ANCOVA), and multivariate analysis of variance (MANOVA). Then, ANOVA is compared with MULTIPLE REGRESSION. The last section introduces some ANOVA examples applied in marketing research.

ANALYSIS OF VARIANCE (ANOVA) AND EXPERIMENTAL DESIGN

ANOVA is used for determining the mean value differences of the dependent variable, (i.e., criterion variable) associated with the effects of the controlled independent variables (i.e., factors, predictor variables) after accounting for the influences of the uncontrolled independent variables (i.e., nuisance variables). In other words, ANOVA is used as a test of mean differences for two or more categories. The null hypothesis for ANOVA indicates that all category means are equal, which suggests that all the categories came from the same overall population. For example, let us suppose that the researcher is interested in examining whether heavy, medium, light, and nonusers of cereals (independent variable with four consumer groups) differ in their preference for Total cereal, measured on a 9-point Likert scale (metric-dependent variable) (Malhotra, 2007). We can use ANOVA to test the null hypothesis that the four groups of cereal consumers have the same preference for Total cereal.

One may wonder whether we can simply use the *t*-test for the same task – determining mean differences across multiple groups. Churchill and Iacobucci (2005) indicate that ANOVA is an extension of the *t*-test in two ways. First, whereas the *t*-test enables us to compare only two sample means at a time, ANOVA lets us compare the means of more than two groups simultaneously. Second, in such a two-sample *t*-test, there is only one factor that defines the group membership (e.g., buyers of brand A as

2 analysis of variance and covariance

opposed to nonbuyers of brand A). In ANOVA, a combination of two or more factors can define the groups (e.g., buyer status and gender).

ANOVA must be composed of at least one dependent variable (e.g., preference for Total cereal) and one or more independent variables (e.g., product use (heavy, medium, light, and nonusers) and shopping frequency (frequent, regular, occasional, and never)). The dependent variables should be metric (i.e., both interval and ratio scales), whereas the independent variables are categorical or nonmetric (i.e., both nominal and ordinal scales). Such categorical independent variables are also called *factors*. A particular combination of factor levels is called a *treatment*. For example, product use is a factor and a heavy-users group in product use is a factor level. A heavy user with regular shopping frequency is a treatment as a combination of the two factors.

One-way ANOVA involves only one categorical independent variable that can influence the dependent variable. When there is only one factor involved in the analysis (e.g., shopping frequency consumer groups – frequent, regular, occasional, and never), we can examine the differences between the specified groups in the factor by one-way ANOVA. In one-way ANOVA, a treatment is considered to be equal to a factor level. If two or more factors are involved, the analysis is generalized to *N*-way ANOVA, where *N* is the number of factors involved. If the researcher needs to compare preferences for Total cereal between brand loyal and nonloyal customers in addition to among the four shopping frequency consumer groups, two-way ANOVA would be appropriate. In this two-way ANOVA analysis, there are eight different treatments from the two factors included (a combination of four factor levels from the shopping frequency factor and two factor levels from the brand loyalty factor). For example, a consumer group who are both occasional shoppers and brand loyal constitute one of the eight possible treatments.

When the analysis takes into account the consumers' interests in their body weights, measured on a 7-point scale as a *metric-independent variable*, the analysis should be upgraded to ANCOVA. In this case, the two categorical independent variables (i.e., shopping frequency and brand loyalty) are still referred

to as *factors*, whereas the metric-independent variable (i.e., attitude toward nutrition) is referred to as a *covariate*. As implied in the example, ANCOVA is used to accommodate both categorical and metric-independent variables simultaneously. ANCOVA is explained in more detail later as a separate section.

From a researcher's perspective, ANOVA is particularly useful when used in combination with an experimental design (see EXPERIMENTAL DESIGN), where the researcher directly controls or manipulates one or more independent variables to measure their effects on the dependent variable. Without such an intended and controlled experimental design, it would be difficult to prove causal relationships between the independent variables and the dependent variable. After all, ANOVA coupled with the experimental design provides the tools necessary to determine whether observed differences between treatment groups are exactly owing to treatment effects or random sampling variabilities (Hair *et al.*, 1995). In brief, the power of the experimental design is that the researcher can actively and systematically alter the variables of interest and observe what changes take place after the manipulation (Cooper and Schindler, 2006). In contrast, to uncover causal relationships, the researcher can interview respondents after the marketing phenomenon took place, as in the *ex post facto* research design. Unlike the experimental design, however, this approach is required to accept the phenomenon as it is unfolded in the world.

ONE-WAY ANALYSIS OF VARIANCE (ANOVA)

According to the number of independent variables used in ANOVA, we can divide the analysis technique into one-way ANOVA (the simplest form) and *N*-way ANOVA (the generalized form). As the name indicates, one-way ANOVA contains only a single independent variable, and, accordingly, cannot have any interaction terms between multiple independent variables. One-way ANOVA can be extended into *N*-way ANOVA, where *N* indicates the number of independent variables in the analysis model. An important addition to *N*-way ANOVA from

one-way ANOVA is the presence of interaction terms of multiple independent variables, in most cases, interactions between two independent variables. One-way ANOVA is explained in this section and the discussion of N -way ANOVA as the general ANOVA model follows in the subsequent section.

Malhotra (2007) effectively illustrates a five-step procedure for implementing one-way ANOVA: (i) identify the dependent and independent variable, (ii) decompose the total variation, (iii) measure the effects, (iv) test the significance, and (v) interpret the results. Let us take a close look at each step one by one.

First, the researcher needs to identify the dependent variable (Y) and the only independent variable (X). The independent variable should be a categorical, nonmetric variable with c categories. Second, the researcher needs to decompose the total variation according to the variation source. In examining the category mean differences of the dependent variable one-way ANOVA divides the total observed variation (SS_y) in the dependent variable into two different components – the variation in the dependent variable related to the variation in the means of the categories of independent variable ($SS_{\text{between}} = SS_x$) and the variation in the dependent variable owing to the variation within each of the categories of the independent variable ($SS_{\text{within}} = SS_{\text{error}}$), which is expressed as follows.

$$SS_y = SS_{\text{between}} + SS_{\text{within}} \quad (1)$$

Whereas SS_{between} represents the variation between the categories of the independent variable, SS_{within} represents the variation not accounted for by the independent variable. Intuitively, we can comprehend the logic of decomposing the total variation of the dependent variable into these two subcomponents in order to examine differences in group means. In ANOVA, there are several different groups (e.g., heavy, medium, light, and nonusers). Using ANOVA, one can determine how much the sample means should vary because of random sampling variation alone. If the observed variation in the sample means is more than what would be expected by sampling variation,

we can conclude that this additional variability stems from group mean differences.

Third, the researcher needs to measure the effects of the independent variable on the dependent variable using $\eta^2 = SS_x/SS_y$. That is, η^2 is a measure of the variation in the dependent variable explained by the independent variable. This measure ranges from 0 to 1. When there is no effect of the independent variable on the dependent variable, $\eta^2 = 0$. Fourth, the researcher can not only measure the effects of the independent variable on the dependent variable using η^2 , but also test for its significance. In particular, in this one-way ANOVA analysis, our interest lies in testing the null hypothesis that the category means of the dependent variable are equal. This null hypothesis is tested by the following F -test statistic based on the ratio between mean square owing to X (MS_x) and mean square owing to error (MS_{error}) (Malhotra, 2007).

$$F = \frac{MS_x}{MS_{\text{error}}} = \frac{[SS_x/(c-1)]}{[SS_{\text{error}}/(N-c)]} \quad (2)$$

As noted above, the mean square is the sum of squares divided by the appropriate degrees of freedom denoted by c .

Lastly, when we interpret the ANOVA results based on the above F -test, there are two possible statistical conclusions: either the null hypothesis is tenable or rejected. If the null hypothesis of equal category means is not rejected, we conclude that the independent variable does not have a significant effect on the dependent variable. On the other hand, if the null hypothesis is rejected, we can conclude that the mean value of the dependent variable will be different across multiple categories of the independent variable. However, when the null hypothesis is rejected, the conclusion, “not all category means are equal,” is not particularly explicit or useful. That is, the rejection of the null hypothesis does not automatically inform the research which means differ significantly from which other means. Therefore, when the null hypothesis is rejected, the researcher needs to learn which means are different from which other means. This search procedure is called a *multiple comparison (MC)* technique (Glass and Hopkins, 1984). The researcher needs to select an appropriate MC technique given the specific research

4 analysis of variance and covariance

objectives. Popular MC techniques include trend analysis, planned orthogonal contrasts (POCs), the Dunnett method, the Dunn method, the Scheffé method, the Tukey method, and the Newman-Keuls (NK) method.

N-WAY ANALYSIS OF VARIANCE (ANOVA)

In addition to an interest in whether an independent variable has an effect on the dependent variable, there may be an interest in whether the factor levels associated with the independent variable are equally effective for the factor levels associated with another independent variable (Glass and Hopkins, 1984). In the context of marketing research, one is often concerned with the simultaneous effects of more than one factor. For instance, the marketing researcher is interested in whether the effects of several brand loyalty levels (e.g., high, medium, and low) vary across consumers' different income levels (e.g., high and low). If the brand loyalty level effects arising from its three different categories vary significantly between high versus low income consumers, we conclude that there is an interaction effect between the two factors of brand loyalty and income. Thus, an interaction occurs when the effects of one factor on the dependent variable depend on the category of another factor. In determining such interaction effects, N -way ANOVA can be used, where N indicates the number of factors or the independent variables. A major advantage of N -way ANOVA compared to the earlier one-way ANOVA is that it enables the researcher to examine these interaction effects between the factors.

Since the basic procedure for conducting N -way ANOVA is similar in many ways to that of one-way ANOVA shown earlier, this section highlights the main differences between the two ANOVA techniques. Although N -way ANOVA can take any number of factors N , we consider a two-way ANOVA that considers two factors (X_1 with c_1 categories and X_2 with c_2 categories) for the sake of simplicity. The total variance in this two-way ANOVA case is partitioned as follows (Malhotra, 2007):

$$SS_{\text{total}} (SS_y) = SS_{x1} + SS_{x2} + SS_{x1x2} + SS_{\text{within}} (SS_{\text{error}}) \quad (3)$$

where, SS_{x1} is SS due to X_1 , SS_{x2} is SS due to X_2 , and SS_{x1x2} is SS due to interaction of X_1 and X_2 as explained below.

A larger effect of X_1 is reflected in a greater mean difference in the levels of X_1 , that is, a larger SS_{x1} . The same is true for the effect of X_2 . By the same token, the larger the interaction effect between the two factors, the larger SS_{x1x2} is. On the other hand, if the two factors are perfectly independent, the value of SS_{x1x2} will be zero. The strength of the overall effect of two factors is measured by multiple $\eta^2 = (SS_{x1} + SS_{x2} + SS_{x1x2})/SS_y$. Then, the significance of the overall effect is tested by the following F -test.

$$F = \frac{[(SS_{x1} + SS_{x2} + SS_{x1x2})/(c_1 c_2 - 1)]}{[SS_{\text{error}}/(N - c_1 c_2)]} \quad (4)$$

Once we conclude a significant overall effect from the above F -test, we need to examine the significance of the main effect of each of the two factors. Specifically, the significance test of the main effect of X_1 is based on the following F -statistics.

$$F = \frac{[SS_{x1}/(c_1 - 1)]}{[SS_{\text{error}}/(N - c_1 c_2)]} \quad (5)$$

The significance test for the main effect of X_2 can be conducted in the same way. Furthermore, we need to test the significance of the interaction effect of the two factors involved in the analysis. For the null hypothesis of no interaction effects, the appropriate F -test is

$$F = \frac{[SS_{x1x2}/\{(c_1 - 1)(c_2 - 1)\}]}{[SS_{\text{error}}/(N - c_1 c_2)]} \quad (6)$$

ANALYSIS OF COVARIANCE (ANCOVA)

ANCOVA is a method of statistical analysis devised by Ronald Fisher in 1932 that combines regression analysis with ANOVA. The procedure involves measuring one or more concomitant variables called as *covariates* in addition to the dependent variable. ANCOVA includes at least one categorical independent variable (factor) and at least one metric-independent variable (covariate) along with one dependent

variable. The most common use of covariates is to remove extraneous variation from the dependent variable because the effects of the factors are of primary interest. For example, in determining how consumers' intentions to buy a brand (dependent variable) vary with different levels of price (factor), age difference (covariate) may have to be taken into consideration. As another example, in determining how multiple groups exposed to different commercials (factor) evaluate the brand advertised (dependent variable), we may want to control for consumers' prior brand knowledge (covariate).

A covariate represents a source of variation that has not been controlled in the experiment and one that is believed to affect the dependent variable (Kirk, 1995). In ANCOVA, the dependent variable can be adjusted to remove the effects of the uncontrolled source of variation represented by the covariates. Its primary advantages are twofold: (i) increase statistical power and (ii) reduce bias (Glass and Hopkins, 1984). That is, ANCOVA is used to produce (i) a reduction in error variance arising from covariates, hence, increased power and (ii) a reduction in bias caused by differences among subjects, where those differences are not attributable to the variation of the independent variable.

MULTIVARIATE ANALYSIS OF VARIANCE (MANOVA)

MANOVA is an extension of ANOVA to accommodate more than one dependent variable. It is a technique that measures the differences for two or more metric-independent variables based on a set of categorical independent variables. It is different from the *N*-way ANOVA that accommodates more than one independent variable but with a single dependent variable. Therefore, ANOVA is called a *univariate procedure* because it is used to assess group differences on a single metric-dependent variable. In contrast, MANOVA is known a *multivariate procedure* because it is used to assess group differences between multiple metric-dependent variables simultaneously. That is, in MANOVA, each treatment group is observed on two or more dependent variables (Hair *et al.*, 1995).

In ANOVA, the null hypothesis is that the means of the dependent variable are equal across

the category groups defined by independent variables involved. The null hypothesis of MANOVA is that the vectors of means on multiple dependent variables are equal across those category groups. MANOVA can be applied when there are two or more dependent variables that are correlated with one another. If there are uncorrelated multiple dependent variables, we can simply use ANOVA for each dependent variable, respectively.

As an example of MANOVA, let us suppose that four consumer groups, each consisting of 100 randomly selected consumers, are exposed to four different commercials about Tide detergent (Malhotra, 2007). After viewing the commercial assigned to the group, each consumer provides his or her own ratings on preference for Tide, preference for Procter & Gamble (the company marketing Tide), and preference for the commercial itself. Because these three preference measures (three metric-dependent variables) are expected to be highly correlated, MANOVA should be conducted to determine the commercial that is the most effective in producing the highest preferences across the three dependent variables. The ANOVA procedure, which can be applied to each dependent variable separately in this example, cannot account for the strong correlations among the three dependent measures.

COMPARISON OF ANOVA AND MULTIPLE REGRESSION

ANOVA and MULTIPLE REGRESSION are two of the most popular statistical analysis tools in marketing research (*see* MARKETING RESEARCH PROCESS). For this reason, they are frequently compared in various ways. On the one hand, the two approaches have much in common, and, accordingly, are categorized into the general linear model. Furthermore, both approaches share the same purpose of explaining the variation in the metric-dependent variable associated with the variation in the independent variables.

On the other hand, comparisons of ANOVA and multiple regression often emphasize differences between the two analysis tools in terms of examining the relationships between the

6 analysis of variance and covariance

dependent variable and independent variables (Kirk, 1995). Notably, the two approaches differ in the nature of the independent variables used. Specifically, in the typical regression application, the researcher is interested in explaining a metric-dependent variable using one or more metric-independent variables. By contrast, in the typical ANOVA application, the researcher is interested in the categorical independent variables that can explain the variation in the metric-dependent variable. However, this difference is blurred when both approaches are extended to accommodate the other type of independent variables. Regression analysis is not restricted to the use of metric-independent variables and can accommodate categorical or nonmetric variables in the form of dummy variables (e.g., males vs. females; buyers vs. nonbuyers). By the same token, ANCOVA, an extended analysis tool of ANOVA, can include metric-independent variables as covariates when they are nuisance variables that need to be controlled for. Even so, ANOVA cannot measure the impact magnitude of each independent variable on the dependent variable as regression analysis does.

From a practical standpoint, ANOVA is appropriate in situations where the independent variable is set at certain specific treatment levels and metric measurements of the dependent variable are obtained at each of the treatment levels considered. Therefore, researchers often rely on ANOVA to analyze data from marketing experiments employing rigorous research designs. For that reason, ANOVA is commonly used in consumer behavior research that often requires a high level of control of the experiment process. For instance, ANOVA would be a proper analysis tool in an experiment in which we select different groups of stores to examine various amounts of in-store promotion for a brand and measure results on the brand sales as the dependent variable (Parasuraman, Grewal, and Krishnan, 2004). In contrast, multiple regression is commonly used in econometric models for marketing problems that use secondary data because it can measure the magnitude of influence of each independent variable on the dependent variable. This type of research does not intend to control the data collection process tightly as with usual consumer behavior research.

APPLICATIONS OF ANALYSIS OF VARIANCE (ANOVA) IN MARKETING RESEARCH

ANOVA can be applied to cases where the researcher is interested in examining the varying effects of categorical independent variables (e.g., different MP3 player brands) on the metric-dependent variable (e.g., consumer satisfaction in music listening). Since the analysis technique has been widely applied in marketing research, particularly in consumer behavior, most marketing research books discuss the technique in varying degrees of detail with practical application examples. Three such examples are briefly introduced here.

First, Cooper and Schindler (2006) use the example of CalAudio, an MP3 manufacturing company. In this example, the marketing manager intends to investigate whether the quality of their MP3 players is affecting their customers' repurchase decisions negatively because their closest competitor's product appears to have fewer repair problems leading to higher customer satisfaction ratings. The manager decides to monitor two measures to assess product quality: adherence to product specifications and time before failure. The specification variable is measured on a 0-to-100 scale, with 100 meeting all product specifications. The time-before-failure variable is calculated in weeks. Furthermore, the management asks the industrial engineering department to develop a modified manufacturing procedure that can improve the product quality measures without decreasing the production rate. After testing the new modified manufacturing procedure, the marketing manager takes a sample of 15 MP3 players made with the old manufacturing method and 15 made with the new method. The players are measured on the two dependent variables – their adherence to product specification and their time before failure. This example is the case of MANOVA because there are two dependent variables (i.e., product specifications and time before failure) with one factor (old vs. new manufacturing procedures).

On the other hand, Malhotra (2009) uses a one-way ANOVA example of Levi Strauss & Company. In his example, the stiff competition in the jeans market forces the company consider three alternative image themes of the

jeans (e.g., “Levi’s. They go on”; “They’re not Levi’s jeans until we say they are”; and “A style for every story”). The researcher assigns a group of respondents to each of the three image themes (independent variable with three categories) and asks each group to evaluate its matched theme by rating it on a 10-point scale (metric-dependent variable).

Similarly, Hair *et al.* (2008) introduce another one-way ANOVA example based on the Santa Fe Grill database. In this case, the owners want to know whether customers who come to the restaurant from greater distances differ from customers who live closer in their willingness to recommend the restaurant to their friends. In this example, there is a single metric-dependent variable (i.e., customers’ willingness to recommend) with two levels of a single factor (customers from greater distances vs. customers who live closer).

cluster analysis

Michel Wedel and Wei Shi (Savannah)

INTRODUCTION

Cluster analysis is a collection of methods for categorizing consumers into clusters that are homogeneous along a range of variables (demographics, attitudes, lifestyles, perceptions). In marketing, it is most often applied for purposes of market segmentation, and the variables that are used to derive the segments are called *segmentation bases*. Other important applications occur in data mining and in perceptual mapping (where products instead of consumers are clustered). An important distinction is between hierarchical and nonhierarchical methods of cluster analysis. Hierarchical methods are “bottom-up” procedures that start with each subject in his/her own cluster and arrive at groupings by successively aggregating the individual clusters. Nonhierarchical methods could be called *top down* and start with some initial allocation of subjects to two or more clusters and employ various algorithms to improve those initial clusters.

HIERARCHICAL CLUSTERING METHODS

The methods in this class all begin with each consumer in an individual cluster. Then, they seek subjects that are similar, and join them to form a cluster. Similarity is defined on the basis of on a (dis)similarity metric between the consumers being clustered. Hierarchical classification methods result in a dendrogram: a tree structure that represents the hierarchical relations among all subjects being clustered. Figure 1 shows an example of such a dendrogram, with consumers labeled A through L.

We can distinguish branches in the tree: the horizontal lines; nodes at which the branches join; and the clusters, groups of subjects joined together in a subtree. The horizontal axis displays the distance between consumers, on the basis of a distance metric defined by the user when running the clustering algorithm. For each node in the graph (where a new subcluster is formed), we can read off the distance at which its elements were linked together into a new cluster, on the horizontal axis. Note that the tree

itself does not define the clusters. One needs to “cut” the tree at certain levels to get clusters of consumers. For example, cutting the tree in Figure 1 at a distance of 20 produces two clusters.

Similarity measures. Most hierarchical clustering methods use dissimilarities or distances between consumers when forming the clusters. Those measures assess how similar or dissimilar the consumers to be clustered are. They are derived from the variables measured on the consumers. The choice of the type of similarity measure used is made by the researcher, and will depend on whether the variables are discrete or continuous as well as on the type of similarity that is desired from a substantive point of view. While there are many such measures, the two most important of these are discussed here.

Continuous variables. The *Euclidian distance* is the geometric distance that one usually computes between two points in space. Assume that two variables are denoted by X_{i1} and X_{i2} have been measured on consumer i . Then, the measure of how (dis)similar consumers i and j are is obtained by plotting them as points, for example, (X_{i1}, X_{i2}) and (X_{j1}, X_{j2}) in the plane spanned by these two variables, and computing the distance between them as

$$d_{ij} = \sqrt{(X_{i1} - X_{j1})^2 + (X_{i2} - X_{j2})^2} \quad (1)$$

The Euclidian distance is thus the square root of the squared differences of the coordinate values of the two points that represent the consumers. For two variables, one can visually plot these two points, but this is a bit more difficult for three variables, and impossible for four or more. However, even in those cases, the Euclidian distance can still be computed: in the case of P variables being measured, the sum in Equation 1 is extended to a sum of P (squared) coordinate differences. A related distance measure is the *Mahalanobis distance*, which corrects for the differences in scales and covariance between the variables. If the covariance matrix is the identity matrix, the Mahalanobis distance reduces to the Euclidean distance.

Figure 1 A dendrogram resulting from hierarchical clustering.

A second measure that is often used for continuous variables, such as lifestyle ratings, is the *Manhattan distance*:

$$d_{ij} = |X_{i1} - X_{j1}| + |X_{i2} - X_{j2}| \quad (2)$$

the sum of the absolute values of the differences of the coordinate values. Again, for P variables, there would be a sum of P terms in Equation 2. Instead of taking the distance of the shortest line between two points in a higher dimensional space, as the Euclidian distance does, the Manhattan distance measures distance by “walking” perpendicular along the coordinate axes, hence its name.

These distance measures need to be computed for all pairs of consumers, leading to $N(N - 1)/2$ distances among N consumers. This is so since the distance from subject i to j is the same as that from j to i , while the distance from subject i to itself is 0. Thus for 10 subjects, there would be 45 distances. The distance matrix has 0 as its diagonal elements, is symmetric, and has nonnegative off-diagonal elements. We could use Euclidian distance, Mahalanobis distance, or Manhattan distance for this matrix.

Table 1 Cross classification of two consumers, i and j , on a number $(a + b + c + d)$ binary variables.

| i/j | Yes | No |
|-------|-----|-----|
| Yes | a | b |
| No | c | d |

Discrete variables. For discrete variables, different (dis)similarity measures need to be computed. Again, while there are many, we discuss two in detail. Assume that there are several binary variables (for example, yes/no readership of 25 magazines) assessed for consumers i and j . Then, a measure of how similar the subjects are on the basis of reading interest could be how often they both do or do not read a magazine. We can cross-classify the two consumers as shown in Table 1.

In Table 1, the number a denotes how often the two share a “yes,” d denotes how often they share a “no,” b and c show how often one reads a magazine and the other does not. Clearly, the higher that a and d are relative to the total, the more similar the consumers may be. Thus, the *simple matching coefficient* of similarity

between consumers i and j is defined as

$$S_{ij} = \frac{a + b}{a + b + c + d} \quad (3)$$

Jaccard's matching coefficient is defined as

$$S_{ij} = \frac{a}{a + b + c} \quad (4)$$

A measure of dissimilarity is obtained (similar to the Euclidian distance, for example) if one computes $1 - S_{ij}$.

The two are similar, but differ in that Jaccard's coefficient does not count joint absence to contribute to similarity, which may be reasonable in some applications. Both Equations 4 and 5 vary between 0 and 1, denoting that the subjects are completely dissimilar and completely similar, respectively.

Again, these distance measures are computed for all $N(N - 1)/2$ pairs of consumers to obtain a distance matrix.

Clustering algorithms. The similarities or distances among subjects constitute the input to hierarchical clustering algorithms. Agglomerative hierarchical methods seek to cluster consumers by agglomerating groups of consumers at successive stages of the algorithm, starting with single-consumer clusters. Several algorithms are available for that purpose. All algorithms start with joining subjects that have the smallest distance (or the largest similarities) into clusters of two consumers. But, they differ in the way they define the distance between a

consumer and a cluster, or between two clusters, in later stages of the algorithm. While such definitions are to some extent arbitrary, they do affect the types of clusters of subjects that are obtained.

At each stage of the *single linkage* (also called *nearest neighbor*) cluster algorithm, the distance between two clusters is defined as the *smallest* distance between any two members of the two clusters. The *complete linkage* algorithm (also called *furthest neighbor*) uses the *largest* distance between any two members of the two clusters to decide which clusters are closest. In *average linkage*, the distance between two clusters composed of several consumers is defined as the *average* distance between all pairs of consumers in the two clusters. In *centroid linkage*, the distance between two clusters is defined as the *Euclidian distance between the centers* of the clusters. Cluster center is computed as the average of the variables for all consumers within the cluster. If the cluster center is instead defined as the median, or most representative consumer in the cluster, *median linkage* is obtained. Figure 2 illustrates all the above cluster algorithms. *Ward's method* uses the *variance* of all observations in two clusters as a measure of the distance between these two clusters. In other words, if all consumers in two clusters combined have a large variance, the distance between these two clusters is large; if they have a small variance, the distance between the two clusters is small, and these clusters will be merged in earlier stages of the algorithm.

The aforementioned distance measures can be used to calculate the *agglomerative coefficient*. It

Figure 2 Illustration of the definition of distance between clusters for various hierarchical clustering algorithms.

4 cluster analysis

indicates the extent to which an existing cluster and the next closest cluster or variable will be combined. We illustrate the relationship between agglomerative coefficient and number of clusters in Figure 3.

NONHIERARCHICAL CLUSTERING ALGORITHMS

The nonhierarchical clustering methods do not derive a tree structure from the data. Rather, they partition the data into a predetermined number of segments, minimizing some criterion of interest. The most popular nonhierarchical algorithm, *K-means* clustering, seeks to minimize the (Euclidian) distances between all consumers within each cluster. The *K-means* procedure starts by assuming a certain number of clusters, say two. It then assigns all subjects to one of the two clusters, and since this is just a way to start the algorithm, a random assignment will do. Alternatively, the algorithm could be initialized by assigning the two consumers that

are farthest apart as the initial cluster centers, and then allocating the remaining consumers to the closest center.

Subsequently, *K-means* computes the centroids of the two clusters by computing the average of the variables across the subjects in each cluster. Thus, if there are, for example, two brand-personality variables on which consumers are to be clustered, one obtains two mean brand-personality scores for each cluster $(\bar{X}_{c1}, \bar{X}_{c2})$, with $c = 1$ and $c = 2$ denoting the clusters. Then, the algorithm moves consumers from one cluster to another, and assigns a consumer to the cluster with the closest centroid. The distance measure of a consumer to a cluster centroid that is used is the Euclidian distance

$$d_{ic} = \sqrt{(X_{i1} - \bar{X}_{c1})^2 + (X_{i2} - \bar{X}_{c2})^2} \quad (5)$$

Then, the algorithm computes the centroids of the clusters again. The algorithm tries all possible transfers of all consumers from one

Figure 3 An illustration of the relationship between agglomerative coefficient and number of clusters. Source: SPSS Tutorial/Cluster Analysis, on judges.sav data.

cluster to the other, and keeps on cycling through all consumers until no more improvement is achieved. Again, this can be extended to P variables by extending Equation 5 to a sum of P terms.

A variant of the K -means algorithm is the *partitioning around medoids* (PAMs). The PAM algorithm works similarly to K -means, but instead of computing the centroids (means of the variables) it computes the medoids, which are the variable values of the most “representative consumer” for each cluster. The medoid is the consumer with the smallest average distance to all other consumers in the cluster in question.

The K -means and PAM algorithms provide a “hard assignment” of all consumers to clusters. In other words, a specific consumer is either member of a cluster 1 or is not. *Fuzzy clustering algorithms* extend this by allowing consumers to have only part membership in each of the clusters, and assign membership values that are between 0 and 1 for each consumer, where the sum of these values is 1. The fuzzy c -means algorithm, for example, works similarly to the K -means, but instead of reassigning consumers to clusters at each stage of the algorithm, it recomputes their fuzzy membership value in each cluster.

NUMBER OF CLUSTERS

In hierarchical methods, one way to identify the optimal number of clusters is to inspect the dendrogram, and hope to find particularly long branches. Such a long branch may indicate that the cluster below it is relatively homogeneous, and therefore one would like to cut the tree at those long branches, yielding two segments, for example, as in Figure 1.

In nonhierarchical methods, the number of clusters is assumed before the analysis (it was assumed to be two above). However, the optimal number of clusters to represent a particular dataset is unknown. One usually tries several values, for example, 2, 3, . . . , 10, and looks at a criterion value to see which solution is the best, which is often conveniently done by plotting the criterion value against the number of clusters. Such a criterion usually is a measure of the within-cluster variability, such as the average within-cluster distance

between subjects (respectively, the percentage of variance explained in the data by the cluster solution). While these measures will always decrease (respectively, increase) if the number of clusters increases, one hopes to find an “elbow” in the curve, yielding a solution after which the decrease (respectively, increase) levels off, or is relatively flat. For hierarchical algorithms, such a plot may be obtained as well, by plotting the number of clusters against the amalgamation coefficient, which is the numerical value of the distance measure used by the specific clustering algorithm, at which clusters merge.

One powerful criterion for nonhierarchical methods is the average *silhouette distance*, which is a measure of the extent to which subjects are misclassified (positive silhouette length values indicate correct classification, negative misclassification). The solution with the larger silhouette distance is the better one, and the silhouette distance should be larger than 0.25. For clustering algorithms, for which a likelihood measure can be computed, standard information statistics such as AIC (Akaike information criterion), BIC (Bayesian information criterion), or CAIC (consistent Akaike information criterion) can be used to select the number of clusters.

RELATIVE PERFORMANCE OF CLUSTERING METHODS

Among the hierarchical methods discussed here, average linkage and Ward’s method are reported to perform best. Single linkage tends to be less stable, and is subject to the emergence of long and ill-separated clusters, a phenomenon called “*chaining*.” One problem in applying the hierarchical clustering methods is the availability of a large number of dissimilarity measures, distances, and clustering algorithms, and the choice among them is often subjective. This holds to a lesser extent for the nonhierarchical methods, which optimize a specific criterion of cluster homogeneity. The nonhierarchical methods are reported to perform better than the hierarchical methods: they are less sensitive to outliers in the data and to irrelevant variables, that is, variables that are present in the data but do not contribute to the cluster solution. However, the nonhierarchical methods are sensitive to the starting solution that is

chosen, and different clustering solutions may be obtained depending on how subjects are allocated to the clusters when starting the algorithm (this is called the *problem of "local optima"*). This holds in particular for large datasets. A hierarchical algorithm may be used to obtain a starting solution for a nonhierarchical algorithm, which tends to improve performance.

CLUSTER VALIDATION

In applications of cluster analysis, cluster validation is important. The final cluster solution may strongly depend on the subjective choice of variables used as a basis for clustering, distance measures, clustering algorithms, and procedures to select the optimal number of clusters. This makes cluster validation essential. There are several ways to validate a cluster solution. The first is *significance testing*. We expect to see the clusters differ in new variables that were not used in the clustering. Often, (multivariate) analysis of variance is used for this purpose, with cluster membership as the independent variables. A note of caution is that testing the variables themselves that were used as input for clustering is inappropriate, and the significance tests between clusters become invalid.

A second powerful way to validate a cluster solution is through *replication*. The dataset is (randomly) split in two or more parts, and the cluster analysis is replicated on the two parts. Consumers in part 2 are assigned to the clusters in part 1, and one checks this corresponds to the clustering of part 2 itself (for example, using cross tabulation). This yields a measure of internal consistency of the cluster solution.

Finally, it is recommended to check *consistency* of the cluster solutions by repeating the clustering with different distance measures and clustering algorithms, and checking whether the solutions obtain correspond (again, cross tabulation can be used).

CLUSTER ANALYSIS SOFTWARE

Software for cluster analysis is widely available. The major statistical packages, including SPSS, S-Plus, BMDP, SAS, STATA, and Minitab have a collection of clustering routines. In addition, R has build-in functions as well as contributed packages for clustering.

For related topics, see LATENT CLASS AND FINITE MIXTURE MODELS.

There is an extensive literature on cluster analysis. Most books on multivariate analysis, or marketing research contain chapters on cluster analysis, for example, Hair *et al.* (1995). The booklet by Aldenderfer and Blashfield (1984) provides a quick yet accurate introduction. Everitt (1993) provides a concise yet condensed description of clustering routines. The book by Rousseeuw and Kaufman (1990) is advanced and detailed, and describes the powerful algorithms that are implemented in the S-Plus and R clustering packages. Wedel and Kamakura (2000) describe clustering methodology and its applications in market segmentation.

conjoint analysis

Vithala R. Rao

INTRODUCTION

Several interdependent decisions are involved in the formulation of a marketing strategy for a brand (of a product or service). These include decisions on not only the product's characteristics but also its positioning, communication, distribution, and pricing to chosen sets of targeted customers. The decisions will need to be made in the wake of uncertain competitive reactions and a changing environment. For a business to be successful, the decision process must include a clear understanding of how customers will choose among (and react to) various competing alternatives. It is well accepted in marketing that choice alternatives can be described as profiles on multiple attributes and that individuals consider various attributes while making a choice. While choosing, consumers typically make trade-offs among the attributes of a product or service. Conjoint analysis (CA) is a set of techniques ideally suited to studying customers' choice processes and determining trade-offs.

CA is probably the most significant development in marketing research methodology over the last 40 years or so. The method has been applied in several thousand applied marketing research projects since its introduction to the marketing researchers in 1971 (Green and Rao, 1971). The method has been applied successfully for tackling several marketing decisions such as optimal design of new products, target market selection, pricing a new product, and competitive reactions. A significant advantage of the method has been the ability to answer various "what if" questions using market simulators; these simulators are based on the results from a conjoint study for hypothetical and real choice alternatives.¹

Five different features of CA have contributed to its versatility for tackling marketing managerial problems: (i) it is a measurement technique for quantifying buyer trade-offs and values; (ii) it is an analytical technique for predicting buyers' likely reactions to new products/services; (iii) it is a segmentation

technique for identifying groups of buyers who share similar trade-offs/values; (iv) it is a simulation technique for assessing new product service ideas in a competitive environment; and (v) it is an optimization technique for seeking product/service profiles that maximize share/return (Green, Krieger, and Wind, 2004).

Against this brief background, this article will be organized as follows. In the next (second) section, principal types of CAs that are in vogue in marketing research are described. In the third section, the process for conducting a conjoint study is briefly described; this section also includes a discussion of various data collection formats and designs for developing stimuli (or profiles) for a conjoint research problem. The basics of conjoint models and estimation are described in the fourth section and a simplified illustration of one approach is provided. In the fifth section, an overview of the variety of applications of this method is presented. A series of recent developments and future directions are enumerated in the sixth section with limited elaboration.

PRINCIPAL TYPES OF CONJOINT ANALYSIS

Over the past several years, various researchers have contributed to the general methodology of CA. The reader is referred to Green and Srinivasan (1978, 1990) for excellent reviews of the field of CA. Essentially, there are four types of conjoint methods; the traditional method (CA) that uses stated preference ratings; the choice-based conjoint analysis (CBCA) that uses stated choices; the adaptive conjoint analysis (ACA) developed in part to handle the issue of a large number of attributes; and the self-explicated CA, which is a bottom-up method. The first three of these can be called *decompositional methods* because the stated preference or stated choice data are decomposed to obtain part-worth functions. The fourth one is called the *compositional method* because it composes a preference score from ratings of scores on attribute levels and relative importances of attributes. We briefly describe each of these.

The traditional CA collects preferences (judgments) for profiles of hypothetical products each described on the entire set of attributes

2 conjoint analysis

selected for the conjoint study. These profiles are called *full profiles*. However, when one concatenates levels of all attributes, the complete set of full profiles (or full factorial design), will in general, be very large. A respondent will be unduly burdened when asked to provide preference judgments on all profiles. Typically, a smaller set of full profiles (selected according to an experimental design) is used in a conjoint study. An individual's overall stated preferences are decomposed into separate and compatible utility values corresponding to each attribute typically using regression-based methods. These separate functions are called *attribute-specific part-worth functions*. In most cases, the preference functions can be estimated at the individual level. This estimated preference function can be deemed as an indirect utility function.

While the traditional decompositional conjoint approach involved full profiles of product concepts described on multiple attributes, several new data collection formats have emerged over the years. A significant development is the use of data on stated choices elicited under hypothetical scenarios that mimic the marketplace and estimating part-worth functions from such data using primarily multinomial logit methods (see LOGIT MODEL); these methods are labeled choice conjoint methods (CBCA or CBC) and have become popular in the early 1990s and are probably the most widely used methods currently. They are based on the behavioral theory of random utility maximization (McFadden, 1974; the origin of this approach is the law of comparative judgment developed by Thurstone (1927). This approach decomposes an individual's random utility for an object into two parts: deterministic utility and random part. Depending on the distributional assumptions for the error part, a number of alternative models are developed to describe the probability of choice of an object. The most popular one is the multinomial logit model (MNL) (see LOGIT MODEL) that uses the extreme value distribution for the error term. These methods belong to the family of discrete choice analysis methods. An excellent volume that elaborates on these stated choice methods is by Louviere, Hensher, and Swait (2000); see also Ben-Akiva and Lerman (1991).

Researchers have also developed an adaptive conjoint method which is called *ACA* (Johnson, 1987). The method involves first a self-explicated task (i.e., eliciting data on attribute importances and attribute level desirabilities using ranking and subsequent rating) followed by preference ratings for a set of partial profiles descriptions, two at a time using a graded, paired comparison scale. The partial profile descriptions are tailored to each respondent based on the data collected in the self-explicated task. Both the tasks are administered by computer. This method is a type of hybrid² model approach.

In contrast, the compositional approach based on the multiattribute attitude models (Wilkie and Pessemier, 1973) estimates preferences from judged values of the components (importances and desirabilities) that contribute to preference. In the compositional approach, individuals are asked to evaluate the desirability of each level of all the attributes as well as the relative importances assigned to the attributes. Then, the preference for any product concept is estimated as a weighted sum of the desirabilities for the specific levels of attributes describing that concept; the weights are the relative importances. This approach is called the "*self-explicated*" method (see Green and Srinivasan, 1978 for more details). Studies have shown that the self-explicated method is surprisingly quite robust (Srinivasan and Park, 1997).

PROCESS OF CONDUCTING A CONJOINT STUDY

In order to provide a context for designing a conjoint study, consider the problem of determining the steady-state demand for a new product. Assume that a sample of n consumers drawn randomly from a total of N customers in the target market for this product was interviewed in a conjoint study. Let q_i denote the quantity of product bought by i th customer in the sample; $i = 1, 2, \dots, n$ (generally measured in the survey) and let p_i denote the probability that the i th customer will purchase the new product in a steady state (conditional on his/her consideration set of alternative items including the new product). Then, the demand forecast

for the new product is given by the model:

$$D = \left(\frac{N}{n}\right) \sum_{i=1}^n q_i p_i$$

The problem then is to estimate the probability of purchase p_i for the new product for the members of the sample. There are at least two solutions for this problem.

One solution is to employ the traditional stated preference-based CA. This method involves obtaining an estimate of the utility a customer derives for a new product described in terms of its attributes relative to other items considered and then translating the utility into probabilities of purchase. Several methods exist for this transformation; see Green and Krieger (1988). The second solution is to utilize the CBCA method. In this approach, the probabilities can be computed directly from the MNL model. Against this backdrop, the process of designing conjoint studies is reviewed.

A typical CA project for collecting and analyzing stated preference or stated choice data³ as such consists of four main steps: (i) development of stimuli based on a number of salient attributes (hypothetical profiles or choice sets); (ii) presentation of stimuli to an appropriate sample of respondents; (iii) estimation of part-worth functions for the attributes as well as any heterogeneity among the respondents; and the use of the estimates in tackling any managerial problems (e.g., forecasting, pricing, or product design). The steps are schematically shown in Figure 1.

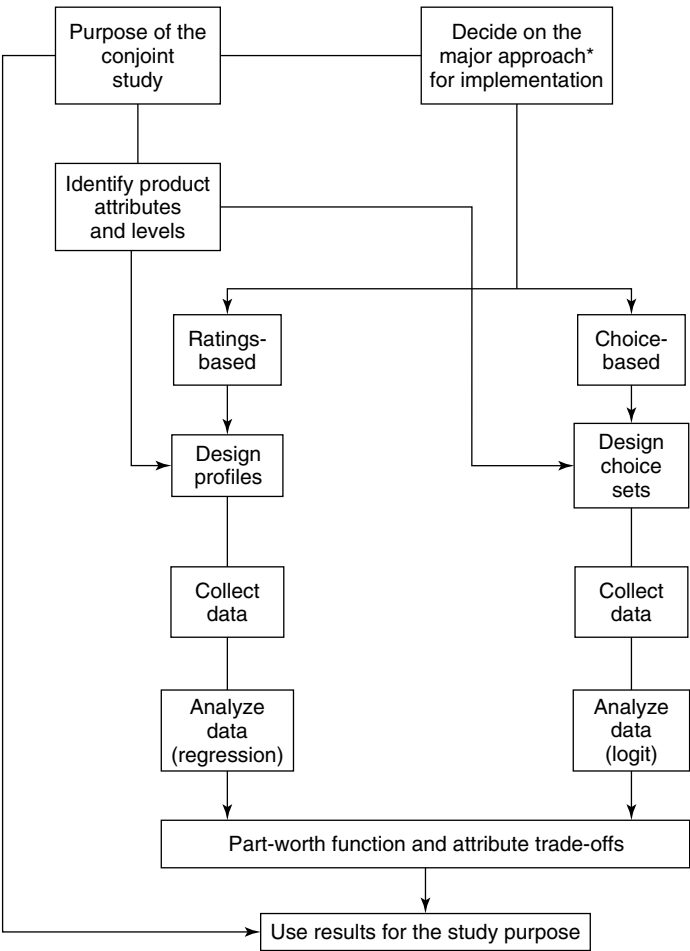

One major step is the design of stimuli (either profiles or choice sets). To illustrate profiles and choice sets, consider a simple conjoint problem with three attributes, A, B, and C, each described at four levels, as a1, a2, a3, and a4. An example profile is (a2, b3, c1) and an example choice set is {(a1, b2, c3); (a2, b1, c4); (a4, b3, c2); (No choice)} with some times “no choice” not included. Stated preference for a profile is measured as a rating or a rank relative to other profiles, while stated choice is the choice made by the respondent among the items in a choice set.

The aspect of designing stimuli (profiles or choice sets) has received much focus since the beginning of CA; it draws much from the theory

of experimental design, where procedures for constructing subsets of combinations of all attribute levels are developed. CA for ratings-based studies makes extensive use of orthogonal arrays (Addelman, 1962; Green, 1974). The process for designing choice sets for collecting stated choice data is a lot more complicated; after developing a number of profiles (usually a subset of all possible profiles), subsets of profiles (4 or 5) are used as choice sets. The “no choice” option is generally included in each choice set. Street and Burgess (2007) present the theory and methods for the construction of optimal stated choice experiments; see also Street, Burgess, and Louviere (2005) and Street and Burgess (2004). Researchers can use the OPTEX procedures in the SAS system (2002–2003) for designing profiles or choice sets; see also Kuhfeld (2005).

In the ratings-based conjoint approach, the respondent is given a number of profiles of product concepts, each described on the attributes under study, and is asked to state his/her preference for each profile on a rating scale (e.g., 10 points or 100 points). These preference data are analyzed using multiple regression methods (typically, a dummy variable ordinary least squares (OLS) regression) to estimate a utility function for each respondent (or for a subgroup of respondents). We illustrate this approach in the next section. Typically, additive utility functions are used although utility functions with interaction terms are possible depending on the experimental designs used for constructing profiles.

The attributes in a conjoint study are of two types: categorical or continuous (or interval-scaled) with only a few selected values (see MODELS FOR CATEGORICAL DEPENDENT VARIABLES). A categorical attribute (such as low, medium, or high) can be converted into a number of dummy variables (one less than the number of levels). A continuous attribute (such as price of a product) can be used directly or can also be converted into dummy variables; if used directly, only a linear term or with both linear and quadratic terms to account for any nonlinear effects can be included in the utility function. With suitable redefinitions of variables, the utility function for the ratings methods can be written as $y = X\beta + \varepsilon$, where

*Several alternatives exist here; two are highlighted.
Source: Rao, V. R. "Developments in conjoint analysis" in B. Wierenga (ed.)
Handbook of marketing decision models, New York: Springer
science + business media, LLC, 2008.

Figure 1 Major steps in a conjoint study (reproduced from B. Wierenga (Ed) Handbook of Marketing Decision Models, © Springer Science + Business Media, LLC, 2008).

ε is the random error of the model assumed to be normally distributed with zero mean and variance of σ^2 , y is the rating on given profile, and X is the corresponding set of p dummy (or other) variables. The model is estimated using regression methods (usually ordinary least squares method; *see* MULTIPLE REGRESSION). The β is a $p \times 1$ vector of regression coefficients associated with the dummy variables or continuous variables included in the model.

The part-worth values for each attribute can be derived from these regression coefficients.

In the choice conjoint methods, the respondent is given a number of choice sets, each choice set consisting of a small number (typically 4 or 5) of profiles, and is asked to indicate which profile will be chosen. An MNL is used for estimating the deterministic component of the random utility using maximum likelihood methods. A variety of extensions and alternatives exist for

analyzing stated choice data. The MNL model (see LOGIT MODEL) for the choice conjoint data is the probability of choosing profile j in choice set $C = \exp(-v_j) / \sum \exp(-v_k)$, where the summation is taken over all the profiles in the choice set C and v_j is the deterministic component of the utility for the profile j . The deterministic utility function v is specified analogous to the linear combination to the function for y in the ratings methods. The estimated coefficients will be used in computing the part-worth values for the attributes in the study.

Current approaches for implementing a CA project differ in terms of several features; some main features are stimulus representation, formats of data collection, nature of data collection, and estimation methods. Table 1 lays out some alternatives for these features. There is no clear agreement as to which data collection format is the best and all the formats shown in Table 1 are in vogue.

One notable development is the use of hierarchical Bayesian estimation methods (see UNOBSERVED HETEROGENEITY) which enable an

analyst to incorporate prior knowledge in the part-worth values as monotonic or other types of order constraints in the estimation process (Allenby, Arora, and Ginter, 1995); see also Lenk *et al.* (1996). Further, part-worth functions are estimated at the aggregate (or subgroup) level or at an individual level. Researchers have also used finite mixture methods (DeSarbo *et al.*, 1992) to “uncover” segments of respondents based on the preference or choice data collected in conjoint studies; see also Andrews, Ansari, and Currim (2002). The variety of recently developed techniques for estimation of part-worth functions is very impressive and a discussion of these is beyond the scope of this article. For a recent discussion of conjoint methods, see Hauser and Rao (2004) and Rao (2008).

BASICS OF CONJOINT MODELS

Conjoint methods are intended to “uncover” the underlying preference function of a product in terms of its attributes⁴. A general product profile defined on r attributes can be written as

Table 1 Alternatives for selected features of conjoint analysis.

| <i>Representation of Stimuli</i> | <i>Formats of Data Collection</i> | <i>Nature of Data Collection</i> | <i>Estimation Methods</i> |
|--|-----------------------------------|----------------------------------|---|

6 conjoint analysis

$(x_{j1}, x_{j2}, \dots, x_{jr})$, where x_{jt} is the level for the j th profile on the t th attribute in a product profile. While there exist several ways for specifying the preference functions in CA, researchers usually start with an additive conjoint model; but, the theory extends to models with interactions as well. The preference score⁵ for the j th product profile, y_j for one respondent additive conjoint model is

$$y_j = U_1(x_{j1}) + U_2(x_{j2}) + \dots + U_r(x_{jr})$$

where $U_t(\bullet)$ is the component utility function specific to the t th attribute (also called *part-utility function* or *part-worth function*). No constant term is specified, but it could be included in any one of the U -functions or assumed to be zero (without any loss of generality). The specification of the U -function for any attribute will depend upon its type (categorical and quantitative). In practice, a conjoint study may contain both types of attributes.

Brand names or verbal descriptions such as high, medium, or low are examples of a categorical attribute; here the levels of the attribute are described by words. A quantitative attribute is one measured by either an interval scale or a ratio scale; numbers describe the "levels" of such an attribute; examples are the weight of a laptop and speed of the processor.

The levels of a categorical attribute can be recoded into a set of dummy variables and a part-worth function is specified as a piecewise linear function in the dummy variables. In this case, the component utility function for a categorical attribute (t th for example) will be

$$U_t(x_{jt}) = D_{i1}U_{t1} + D_{i2}U_{t2} + \dots + D_{ir_t}U_{tir_t}$$

where r_t is the number of discrete levels for the t th attribute (resulting from the construction of the profiles or created ex post); D_{ik} is a dummy variable taking the value 1 if the value x_{it} is equivalent to the k th discrete level of x_t and 0 otherwise; and U_{tk} is the component of the part-worth function for the k th discrete level of x_t . In practice, only $(r_t - 1)$ – one less the number of discrete levels of the attribute – dummy variables are necessary for estimation.

A quantitative attribute can be used in a manner similar to a categorical attribute by

coding its values into categories or used directly in the specification of the part-worth function for the attribute. In the latter case, the function can be specified as linear (vector model) or nonlinear; one example of a nonlinear function is the ideal point model. Mathematically, the component utility function can be specified as

$$U_t(x_{jt}) = \begin{cases} w_t x_{jt} & \text{for the vector model; and} \\ w_t (x_{jt} - x_{0t})^2 & \text{for the ideal point model;} \end{cases}$$

where w_t is a weight (positive or negative) and and x_{0t} is the ideal point on the t th attribute.

A linear function is appropriate for an attribute deemed to be desirable (e.g., speed of a laptop computer) or undesirable (e.g., weight of a laptop computer); such a function is called a vector model for which the utility increases (or decreases) linearly with the numerical value of the attribute.

As mentioned above, with suitable redefinitions of variables, the preference function can be written as $y = X\beta + \varepsilon$, where ε is the random error of the model assumed to be normally distributed with zero mean and variance of σ^2 ; y is the rating on a given profile; and X is the corresponding set of p dummy (or other) variables. The β is a $p \times 1$ vector of part-worths among the levels of attributes.

At this point, it will be useful to indicate the software available for designing and implementing conjoint studies. These are

- Sawtooth Software (ACA, CBC, etc.; probably the most complete solution)
- SPSS (useful for preference-based approach)
- SAS (OPTEX for design and several other programs for analysis)
- LIMDEP (useful for analyzing data of various types; Greene, 2003)
- Bayesm package in R (developed by Rossi, Allenby, and McCulloch, 2005)
- MATLAB (one needs to develop a specific program code).

Table 2 Variable smart phone attributes.

| Attribute | Levels | | | |
|--|--|--|---|---|
| | 1 | 2 | 3 | 4 |
| Style | Candy bar  | Slide phone  | Flip phone  | Touch screen  |
| Brand | Blackberry | Nokia | LG | Samsung |
|     | | | | |
| Talk time | 3 h | 5 h | 7 h | 9 h |
| Weight | 100 g | 115 g | 130 g | 145 g |
| Camera quality | 2 MP | 3 MP | 6 MP | 8 MP |

AN ILLUSTRATION OF RATINGS-BASED
CONJOINT ANALYSIS

As an illustration of the ratings-based conjoint method, assume that a wireless provider firm is interested in determining trade-offs among various features of a smart phone (a technologically advanced product with a number of features). In order to simplify the data collection, assume that the firm is interested in the trade-offs among five attributes, namely, style of the phone, brand name, talk time, weight, and camera quality (having predetermined a number of standard features). Price attribute was not included because it was part of a contract with the wireless provider and was about the same for all brands. Each of these five attributes is varied at four levels. Table 2 shows the features that are predecided and the levels of the five features varied in the study.

The total number of possible hypothetical profiles are 1028 ($= 4 \times 4 \times 4 \times 4 \times 4$), which are combinations of the levels of the five attributes. Given that it is almost impossible to have a respondent judge all these profiles, the study designer has selected 32 of these profiles using a fractional factorial design. In the study, respondents were shown the complete list of standard features and were asked to provide preferences on a 0–100 point scale for the 32 profiles. These profile descriptions were provided using a computerized questionnaire. The results from an analysis of one respondent's evaluations are shown. These data are analyzed using dummy variable regression after converting each attribute into three dummy variables as shown in Table 3 to obtain part-worth functions for the five attributes. The resulting regression and part-worth values are also shown in Table 3. The range of each part-worth function is a simple measure⁶ of the importance of that attribute. Figure 2 shows the plots of part-worth functions for the five attributes.

Although not shown, the fit of the part-worth model to the individual's preference ratings is quite good with an adjusted R-square of 0.88. On the basis of this analysis, one can conclude that this respondent has a strong preference for a flip style Blackberry smart phone that is lightest in weight with a talk time of 9 hours and a camera quality of 6 MP. From the graphs

Figure 2 Part-worth functions for the smart phones illustration weight.

Table 3 Estimated part-worth values for the illustrative data for smart phone study.

| Attribute | Level | Recoded Dummy Variables | | | Part-worth Value | Relative Importance(%) |
|----------------|--------------|-------------------------|----|----|------------------|------------------------|
| | | D1 | D2 | D3 | | |
| Brand | Blackberry | 1 | 0 | 0 | 7.25 | 17.86 |
| | Nokia | 0 | 1 | 0 | 4.63 | |
| | LG | 0 | 0 | 1 | 2.87 | |
| | Samsung | 0 | 0 | 0 | 0.00 | |
| Style | Candy bar | 1 | 0 | 0 | −0.97 | 26.42 |
| | Flip | 0 | 1 | 0 | 9.95 | |
| | Touch screen | 0 | 0 | 1 | 7.58 | |
| | Slide | 0 | 0 | 0 | 0.00 | |
| Talk time | 3 h | 0 | 0 | 0 | 6.99 | 21.84 |
| | 5 h | 0 | 0 | 1 | −1.88 | |
| | 7 h | 0 | 1 | 0 | 2.12 | |
| | 9 h | 1 | 0 | 0 | 0.00 | |
| Weight | 100 g | 1 | 0 | 0 | 7.88 | 19.4 |
| | 115 g | 0 | 1 | 0 | 6.01 | |
| | 130 g | 0 | 0 | 1 | 1.89 | |
| | 145 g | 0 | 0 | 0 | 0.00 | |
| Camera quality | 2 MP | 0 | 0 | 0 | 0.00 | 14.48 |
| | 4 MP | 1 | 0 | 0 | 1.22 | |
| | 6 MP | 0 | 1 | 0 | 5.88 | |
| | 8 MP | 0 | 0 | 1 | 5.15 | |

of the part-worths, one can see that the decline in utility from these levels of the attributes to other levels is not uniform. Further, there is nonlinearity in the part-worth function for the attribute of the camera quality. Looking at the relative importances, this individual places most importance for the style attribute followed by talk time, weight, brand, and camera quality in that order. The part-worth functions can be sued to predict the individual's preference rating for a profile not covered in the 32 profiles. Further, one can estimate preferences for items in any choice set; these estimates can be used to predict the individual's first choice and other choices. Also, if the study is conducted for a sample of respondents, the vector of estimated relative importances can be used to form clusters of individuals whose importances are quite similar; these clusters are akin to market segments. Focusing on one brand (e.g., LG), one can make predictions of first and other choices for the sample for various scenarios (e.g., anticipated changes in the product designs of competing

brands); such a process is the simulation aspect of CA, which is highly useful for managers.

APPLICATIONS

Since its introduction, conjoint methods have been applied in a large number of applied marketing research projects. There is no recent estimate of the number of applied studies but its use is increasing tremendously. The conjoint methodology has been applied in several areas; these include consumer nondurable products (bar soaps, carpet cleaners, lawn chemicals, etc.), industrial goods (copying machines, portable computer terminals, personal computer design, etc.), other products (car batteries, ethical drugs, pesticides, etc.), financial services (branch bank services, auto insurance policies, credit card features, etc.), transportation (domestic airlines, electric car design, etc.), and other services (hotel design, car rental agencies, telephone pricing, etc.). The method has been applied

successfully for tackling several marketing decisions such as the optimal design of new products, target market selection, pricing a new product, and studying competitive reactions. Some high profile applications of these techniques include the development of Courtyard Hotels by Marriott (Wind *et al.*, 1989) and the design of the E-Z Pass Electronic Toll Collection System in New Jersey and neighboring States in the United States (Green, Krieger, and Vavra, 1997). A significant advantage of the conjoint method has been the ability to answer various “what if” questions using market simulators; these simulators are based on the results of an analysis of conjoint data collected on hypothetical and real choice alternatives.

SOME RECENT DEVELOPMENTS

We have mentioned the development of hierarchical Bayesian methods and experimental design described earlier in the article. In addition, there have been developments on dealing with a positive part-function for price (Rao and Sattler, 2003), use of incentive-aligned methods for data collection (Ding, Grewal, and Liechty, 2005; Ding, 2007), a range of methods for handling large number of attributes (reviewed in Rao, Kartono, and Su, 2008), polyhedral methods aimed at reducing respondent burden (Toubia *et al.*, 2003; Toubia, Hauser, and Simester, 2004), and modeling choices for bundles (Bradlow and Rao, 2000; Chung and Rao, 2003) and upgrading methods (Park, Ding, and Rao, 2008) based on the BDM method (Becker, DeGroot, and Marschak, 1964), experimental designs based on new criteria such as utility balance (Huber and Zwerina, 1996; Hauser and Toubia, 2005), continuous CA (Wittink and Keil, 2003; Su and Rao, 2006), adaptive self-explicated analysis (Netzer and Srinivasan, 2007), and measuring reservation prices for single products and bundles (Jedidi and Zhang, 2002; Jedidi, Jagpal, and Manchanda, 2003). These are but only a few examples of continuous developments in CA research. The article written from the 2007 Choice Symposium, Netzer *et al.* (2008) identifies several new directions in this methodology; see also Hauser and Rao (2004), Bradlow (2005), and Rao (2008) for ideas for

future research in this area. In conclusion, one might say that CA is alive and well!

ENDNOTES

¹ It will be useful to review some terms used in conjoint analysis. Attributes are (mainly) physical characteristics that describe a product; levels are the number of different values an attribute takes; profile is a combination of attributes, each attribute at a particular level, presented to a respondent for an evaluation (or stated preference); choice set is a pre-specified number of profiles presented to a respondent to make a pseudo-choice (stated choice).

² Hybrid models involve a combination of several tasks aimed to increase the “efficiency” of data collection in conjoint studies usually for large number of attributes. See Green (1984) for a review of these methods; see also Green and Krieger (1996). We will not delve much into these methods due to space limitations.

³ For the sake of ease in exposition, we will restrict to these two types of data and will not delve into methods that involve variations such as the hybrid methods.

⁴ For an introduction to conjoint analysis, see Orme (2006).

⁵ For exposition purposes, I am considering a ratings-based conjoint analysis where respondents provide preference ratings for a number of product profiles. The same can apply to the v-function in the choice-based conjoint analysis.

⁶ There are several other measures such as partial R-squared but are beyond the scope of this chapter.

exploratory factor analysis

Michel Wedel and Wei Shi (Savannah)

FACTOR ANALYSIS AND PRINCIPAL COMPONENTS ANALYSIS

Factor analysis is not a single method, but in fact a group of methods with unprecedented popularity in marketing research. It is applied as a “data-reduction” or as a “latent-structure” detection method. In the first application we are in the domain of data mining, in which factor analysis continues to be a popular and powerful tool. The second type of application often occurs in market structuring based on subjective judgments, and in perceptual mapping. The main purposes of factor analysis are (i) to reduce the number of variables in a dataset, (ii) to explore relationships among those variables, and (iii) to detect latent dimensions (factors) underlying the relationships between observed variables. Two sets of goals, (i) and (ii) and (ii) and (iii), correspond to two different variants of factor analysis: principal components analysis (PCA) and factor analysis in the strict sense, respectively.

THE BASIC IDEA

Suppose we want to measure satisfaction with an administrative computer system, among a sample of $i = 1, \dots, N$ consumers. We design a satisfaction questionnaire in which we ask our consumers how satisfied they are with hardware reliability (X_{i1}), with software reliability (X_{i2}), with the ease of maintaining the hardware (X_{i3}), and with the ease of maintaining the software (X_{i4}). Most likely, the responses to the four questions are correlated with each other. From relatively high correlations among the variables, we can conclude that there is a certain degree of redundancy between them. Therefore, one may wish to combine the original variables into a single new one that captures the essential information. One way to do this is to sum the responses to all questions, for each consumer. Let us call this new variable a *factor* (or alternatively a *component*; please note that the word “factor” is used in different ways in statistics: it can also be used to indicate a categorical variable

with a finite number of levels, such as education). The score for consumer i on the new factor is obtained from the following equation:

$$PC_i = X_{i1} + X_{i2} + X_{i3} + X_{i4} \quad (1)$$

We have achieved parsimony, since instead of the four original variables, we now have one new variable, or factor, and we have the “score” of each consumer on that new factor, or principal component (PC is an abbreviation of principal component, another term for factor).

The question is, however, whether summing is the best way to combine the observed X -variables. For example, the redundancy between the reliability items (X_{i1} and X_{i2}) may be large and the redundancy between the maintenance questions (X_{i3} and X_{i4}) may be large, but the redundancy between these two sets may be limited. In other words, consumers’ scores on reliability items are correlated, and those on maintenance questions are correlated. Alternatively, there might be redundancy (correlation) between the hardware (X_{i1} and X_{i3}) and between the software (X_{i2} and X_{i4}) variables respectively, but not between those two groups of variables. Thus, a better way to combine those variables could be to use weights to obtain the scores on the new factor:

$$PC_i = W_1X_{i1} + W_2X_{i2} + W_3X_{i3} + W_4X_{i4} \quad (2)$$

Here, instead of summing the variables, a weighted combination of the variables is computed, with four weights, one for each variable: W_1, W_2, W_3, W_4 . The question, of course, is how can we get those weights? We can set these weights manually, according to a priori notions of how the variables are to be combined. The simpler Equation 1 is obtained by setting all weights to 1. Alternatively, we could construct a new factor as in Equation 2, by summing all hardware questions (set their weights to 1, weights for software to 0). Or we could construct a “software factor” by summing all software questions (set their weights to 1, weights for hardware to 0).

We could also choose to set the weights based on the correlations between the variables, where

2 exploratory factor analysis

those variables that correlate highly are weighted together. This has the advantage that we let the data tell us the variables that are to be combined into the factor, rather than making the decision ourselves a priori. For example, if there is much redundancy among the questions X_{i1} and X_{i2} of reliability of software and hardware, as evidenced by a high correlation among them, we would want to give X_{i1} and X_{i2} high weights (i.e., W_1, W_2 are large). However, since now the maintenance variables X_{i3} and X_{i4} receive low weights, we get little information on them. But if these two variables are highly correlated as well, we may wish to form a second factor, independent of the first, that has large weights for the two maintenance variables (i.e., W_3, W_4 are large). Thus, we now have two equations, one for each factor:

$$\begin{aligned} PC_{i1} &= W_{11}X_{i1} + W_{21}X_{i2} + W_{31}X_{i3} + W_{41}X_{i4} \\ PC_{i2} &= W_{12}X_{i1} + W_{22}X_{i2} + W_{32}X_{i3} + W_{42}X_{i4} \end{aligned} \quad (3)$$

As mentioned above, if we want the first factor to be only a combination of X_{i1} and X_{i2} and the second factor to capture the information in X_{i3} and X_{i4} , we could set $W_{31} = W_{41} = W_{12} = W_{22} = 0$. Although we have two factors, we have obtained parsimony, since, instead of the original four variables, we now have two new factors that we can work with. In general, having the data tell us what the weights should be is a better idea.

If we have a large number of variables, we may want to compute more than two factors. The problem then becomes somewhat more complicated, since we need to choose many weights based on the correlations between the variables. In the above case of four variables and two factors, we have $2 \times 4 = 8$ weights to choose; in the general case of J variables and P factors we have $J \times P$ weights. The problem is complicated even more if we do not know beforehand how many factors we want to extract (for example, in the example above it might not be clear whether we want to combine the variables based on reliability-maintenance, software-hardware distinctions, or both). PCA can do this for us: it estimates the weights based on the correlation of the variables, and helps us to choose the correct number of factors to be derived from the data.

PRINCIPAL COMPONENT ANALYSIS

As mentioned above, the purpose of PCA is data reduction. We have observed J variables, but would like to work with P components instead ("components" is used rather than "factors" in this section, which is just a matter of conforming to the standard terminology). P is smaller than J . We call the principal components approach *formative*, since it "forms" the components from the observed variables as in Equation (3). Later, we will distinguish this from the "reflective" factor analysis procedure. PCA is not a statistical model, but a data-analysis or data-mining tool to reduce the data and explore meaningful patterns. This will be explained in a bit more detail below.

Estimation of the model is not discussed here. It suffices to mention that it is based on a mathematical technique called *eigenvalue decomposition*. This method has the interesting property that, based on the correlation matrix of the variables as input, it provides us with those components that explain the maximum percentage of variance in all original variables (similar to the way a linear regression explains the maximum amount of variance attainable in a single y -variable). Note, however, that PCA does not distinguish between X - and Y -variables. Equation 3 looks similar to a regression equation, but there are important differences. First, a key difference is that not only the weights W_{ip} but also the "dependent variables" PC_{ip} are unknown. Second, there are multiple "dependent variables" PC_{ip} that are modeled simultaneously. Third, the PCA formulation does not contain error terms (see Equation 3, for example), owing to which it is merely a convenient mathematical representation of the data that does not allow for statistical testing.

An interesting property of the eigenvalue decomposition method is that the components extracted are independent, which makes their interpretation easier than that of the original variables. PCA uses the correlation matrix of the variables as input. The output produced by computer programs that use the eigenvalue decomposition to estimate principal components is discussed below. An example of the output is given in Table 1. Variables are shown in the first column, the columns labeled *Comp#* are the three extracted components, and *Comm* is the

Table 1 Loadings matrix estimated with PCA.

| <i>Variable/Factor</i> | <i>Comp 1</i> | <i>Comp 2</i> | <i>Comp 3</i> | <i>Comm</i> |
|-------------------------|---------------|---------------|---------------|-------------|
| Software reliability | 0.24 | −0.38 | 0.53 | 0.48 |
| Hardware reliability | 0.27 | −0.26 | 0.48 | 0.37 |
| Performance | 0.30 | −0.21 | — | 0.13 |
| Upgradability | 0.27 | — | −0.42 | 0.25 |
| System manageability | 0.29 | −0.22 | — | 0.13 |
| Service manageability | 0.29 | — | −0.34 | 0.19 |
| Ease of configuration | 0.28 | — | −0.26 | 0.14 |
| Ease of maintainability | 0.29 | — | −0.22 | 0.13 |
| Servicability | 0.28 | 0.34 | — | 0.19 |
| Mechanical design | 0.27 | 0.45 | — | 0.27 |
| Electrical design | 0.27 | 0.44 | — | 0.26 |
| Software compatibility | 0.29 | — | — | 0.08 |
| Hardware compatibility | 0.28 | 0.28 | — | 0.16 |
| Eigenvalue | 1.00 | 0.88 | 0.91 | — |
| Cumulative % explained | 0.56 | 0.65 | 0.71 | — |

column with communalities. We use this table to illustrate the main concepts of PCA.

- *Loadings.* Rather than referring to W_{ip} as weights, in PCA one refers to them as *loadings*. They represent the contribution of a variable to a component, and can be interpreted as the correlation between the (unobserved) component and the (observed) variable. Like correlations, loadings can be between minus one and one. For example, the first variable in Table 1, software reliability, has a loading of 0.24 for the first, and −0.38 for the second component. Thus, software reliability correlates positively with the first component, while it has a negative correlation with the second. Thus, consumers that have higher scores for software reliability tend to score higher on component 1, but lower on component 2. The square of the loading is the percentage of the variance in the variable accounted for by the factor: it would be 14.4 and 5.8%, respectively for components 1 and 2, for software reliability.
- *Eigenvalue.* A PCA provides one “eigenvalue” for each component extracted. The term *eigenvalue* derives from the technique used to derive the components (eigenvalue decomposition). That value is proportional to the percentage of variability in all variables explained by that component. In Table 1, the

first component has an eigenvalue of 1.00, and explains 56% of the variability in all variables (that percentage is obtained by dividing the eigenvalue by the sum of the eigenvalue of all components).

- *Communality.* The communality represents the percentage of variance in a specific variable, accounted for by all the components and is thus a number ranging from zero to one. It is shown as the rightmost column in Table 1. For example, the PCA explains 48% of the variance in the software reliability variable. It is the sum of the squared loadings in that row of the table; here, it is $0.38^2 + 0.24^2 + 0.53^2 = 0.48$. The communality helps us to inspect to what extent the analysis captures the variability in each of the original variables. Some statistical packages compute *uniqueness* instead of communality. Uniqueness is equal to $1 - \text{communality}$, so that in the example above it is $1 - 0.48 = 0.52$. Uniqueness is the variance in a particular variable, unexplained by the components. It is that part of the variable which is unique to it, and hence its name.

How to select the number of components. In most applications of PCA, the number of components is unknown. How many components to extract from the data is an arbitrary decision to a certain

4 exploratory factor analysis

extent. In principle, one could extract as many components as there are variables, but in most applications this is not a very useful thing to do because it does not yield any reduction in the data. Here we provide some guidelines that are commonly used, and that, in practice, seem to yield good results.

First, we can retain only components with *eigenvalues greater than 1*. In essence this is like saying that, unless a component extracts at least as much as the equivalent of one original variable, we drop it. The “eigenvalue larger than 1” criterion is probably the one most widely used. In our example above, using this criterion, we have retained one component, since it has an eigenvalue larger than 1. This criterion is a conservative criterion in most applications, since it provides an upper bound to the number of components to retain, and, in most applications, will indicate too large a number of components.

A graphical method to select the number of components is the *scree test*. In this test, one plots the eigenvalues (or equivalently the percentages

of variance explained by the components) in a simple line or bar plot against the component number. Figure 1 provides an example (generated with the statistical package S-PLUS). Then, we need to find the place where the smooth decrease of eigenvalues appears to level off when moving from left to right in the plot. To the right of this point, presumably, one finds only “scree” (“scree” is the geological term referring to the debris that collects on the lower part of a rocky slope). Or equivalently, one would look for a jump in this plot. According to this criterion, we would probably retain two or three components in Figure 1. In Figure 1, the horizontal line indicates the “eigenvalue equals to 1,” and it is clear that this criterion would indicate a much larger number of components (eight).

Component scores. Once we have estimated the weights or loadings, we can compute each consumer’s score on the components, using Equation 3. For example, for a particular consumer, Joe, we substitute in Equation 3 his values $X_{Joe,1}$, $X_{Joe,2}$, $X_{Joe,3}$, and $X_{Joe,4}$ for the

Figure 1 Illustration of a scree plot that plots the relative importance (eigenvalue, variance, and percentage variance explained) of the components.

measured variables, and then substitute the estimated weights $W_{11}, W_{21}, W_{31}, W_{41}$. This gives us a score $PC_{Joe,1}$ for Joe on the first component. For each consumer i , we get a score for each of the P ($P = 2$ in Equation 3) components: PC_{ip} . We can save those scores as (two) new variables in our dataset and use them in subsequent analyses instead of the original variables. A benefit is that these scores are independent. For example, these scores are often used as x -variables in a regression analysis.

Biplot. The biplot is a joint plot of the component loadings and the scores, for two components (usually component 1 and 2, but any other combination of components is possible). Figure 2 provides an example of a biplot, generated with S-PLUS. In that plot, each variable is represented as a line emanating from the origin, and the endpoint of that line is a point that corresponds to the loadings of the variable on components 1 and 2. Each consumer is represented as a point, corresponding to that consumer's scores on components 1 and 2. This allows us to assess the relationships between the variables (variables that are close together in the plot are highly correlated). Also, it enables inspection of the components' scores and their relation to the variables. Two consumers that are close together have similar scores on the components and similar values for the measured variables. Further, one could project the location of a consumer orthogonally on one of the lines representing the original variables. The length of that projection (either positive or negative) tells us whether the consumer scores high on that variable. Thus, the biplot provides a very parsimonious two-dimensional graphical representation of relationships between the rows and columns in the dataset.

FACTOR ANALYSIS

Factor analysis is related to PCA. But it differs from factor analysis in that it is not a data-reduction tool, but a statistical model, often called a "*measurement model*." In a factor analysis model, the left- and right-hand sides of

Equations 3 are reversed:

$$\begin{aligned} X_{i1} &= W_{11}F_{i1} + W_{12}F_{i2} + e_{i1} \\ X_{i2} &= W_{21}F_{i1} + W_{22}F_{i2} + e_{i2} \end{aligned} \quad (4)$$

$$\begin{aligned} X_{i3} &= W_{31}F_{i1} + W_{32}F_{i2} + e_{i3} \\ X_{i4} &= W_{41}F_{i1} + W_{42}F_{i2} + e_{i4} \end{aligned} \quad (5)$$

Thus factor analysis specifies a relation between the observed variables (X_{i1}, \dots, X_{i4}), and the unobserved factors (F_{i1}, F_{i2}) and error terms (e_{i1}, \dots, e_{i4}). Note that in Equation 4, the factors as well as the weights on the right-hand side of the equality sign are all unobserved. The model is a statistical model, since it also includes measurement error. It is called a *reflective model*, since it assumes that the unobserved factors are *reflected* in the observed X -variables. This model is often used in measurement problems in marketing, including the measurement of perceptions, attitudes, and so on, as well as in multidimensional scaling, perceptual mapping, and product positioning. The basic idea is that consumers hold only a limited set of perceptions (the factors) that are covered by asking questions on a wide range of observed variables.

Factor analysis and PCA are often confused with one another because the estimation methods for the two models may be similar: the eigenvalue decomposition can be used for both. However, whereas the purpose of PCA is data reduction, that of factor analysis is the identification of latent dimensions. Thus factor analysis requires more theoretical/substantive input: the researcher should know that there are factors, unobserved dimensions, and underlying consumers' responses to a series of measurement scales (often five-, seven-, or nine-point likert scales). However, the researcher does not need to know how many of those factors are there, or what their nature is. If the researcher has precise knowledge on what the number of factors and how they relate to the observed variables, *confirmatory factor analysis* should be applied.

Estimation and number of factors. The eigenvalue decomposition is just one (the simplest) way of estimating factor models; better methods are principal axis factoring (PAF) and maximum likelihood (ML). Both methods are iterative,

Figure 2 Illustration of a biplot, with the numbers corresponding to consumers and the lines corresponding to measured variables.

but their description is beyond the scope of the present article. ML estimation presupposes that the X -variables all have a normal distribution. This has the advantage that it allows for statistical significance tests for the number of factors and loadings. But in most cases, the number of factors is selected with a scree plot very similar to the one described above for the case of PCA.

Rotation and interpretation of results. We could plot the factor loadings as shown in a biplot (Figure 2). An unrotated factor loading result may be hard to interpret. A common pattern is that nearly all variables have high loadings on the first factor. We solve this problem through rotation. Note that in the biplot, we can rotate the axes in any direction without changing the relative locations of the variables (or the consumers) to each other; however, the actual coordinates of the points, that is, the factor loadings would, of course, change. This rotational indeterminacy is caused by the fact that a factor solution is not unique (that is, there are many different sets of

loadings and scores that would give us exactly the same fit to the observe data). That nonuniqueness may help us to obtain a solution that is more easily interpretable. There are various rotation methods that have been proposed. *Varimax Rotation* is the most often used method. The goal of all of these is to obtain a clear pattern of loadings, that is, factors that are somehow clearly marked by high loadings for some variables and low loadings for others. From the rotated factor matrix, the factor loadings can be interpreted or named by the variables that have higher loadings. Such patterns are sometimes referred to as *simple structure*.

SOFTWARE

Software for PCA and factor analysis is widely available. The major statistical packages, including SPSS, S-PLUS, BMDP, SAS, STATA, and Minitab have a collection of routines and R has build-in functions as well as contributed packages.

For related topics, see the articles CONFIRMATORY FACTOR ANALYSIS; STRUCTURAL EQUATION MODELING.

There is an extensive literature on factor analysis. Most books on multivariate analysis or marketing research contain articles on cluster analysis; see, for example, Hair *et al.* (1995) for an accessible introduction, and Dillon and Goldstein (1984) for a more extensive, yet very clear, exposition.

hypothesis testing related to differences –
parametric tests

Marcus J. Schmidt

DECISIONS UNDER UNCERTAINTY

Every day we make lots of decisions. The majority of our decisions are of minor importance and the outcomes have limited consequences in our lives. On a given occasion, we decide which retail store we want to shop at, which road to drive on, which clothes to wear, and so on. However, now and then our decisions are important, implying that it is vital for us to make the best of alternating choices. Finding a spouse, choosing a job, purchasing a house, and selecting a school for our child are examples of essential decisions. Many important decisions are related to our work: selecting a supplier, hiring or firing personnel, inventing new technology, changing the production process, and launching a new product. In business settings, it is important that we get things right because making an inappropriate decision may have fatal consequences for the company in terms of economic losses and missed opportunities. Sometimes, wrong management choices even lead to bankruptcy. The financial crises that arose in 2008 may serve as an example.

Since decisions have consequences, management often chooses to use relevant quantitative data as input to the decision-making process. Prior to inventing a new *production process* (see PROCESS INNOVATION), management might want to collect empirical support on whether the new process significantly lowers production costs, whether it improves the job satisfaction of employees, and so on. Likewise, before *launching a new product* (see LAUNCH STRATEGIES), management might wish to collect empirical support on whether customers are expected to purchase the new product instead of or in addition to the old product or if they may consider switching from the competitor's brand to the company's new brand.

In an ideal world, it is preferable to collect data on all relevant subjects and objects, that is, conduct interviews with all the company's actual and potential customers, record every production run, and so on. However, owing to

time and cost considerations, collecting data from the whole universe (N) is rarely possible. Instead, companies, in most cases, base the data collection on a *survey* (see SURVEY RESEARCH) where a *sampling technique* (see SAMPLING TECHNIQUES) is employed for collecting a *reliable and valid* (see RESEARCH RELIABILITY AND VALIDITY) representative subset of N called n .

While limiting data collection to n instead of N has obvious advantages, it also has a disadvantage: sampling error. It may be difficult to prove that n is a valid representation of N .

Assume that management has a well-specified goal concerning customer satisfaction: More than 80% of its 200 000 customers must be either "satisfied" or "totally satisfied" with the company's service. Next, a study carried out by a market research agency among 500 customers shows that 84.3% of customers report to be (totally) satisfied. If we had been interviewing all 200 000 customers, we would have been sure that we had reached our success criteria: our goal would be $>160\,000$ satisfied customers ($0.8 \times 200\,000$) while the empirical data showed 168 600 ($0.843 \times 200\,000$). However, because we have been sampling only 0.25% ($500/200\,000$) of the population, we need to consider possible errors caused by the sampling process (in the following we assume that all errors are chance based).

While 0.843 is greater than 0.80, our empirical sample is only one of an endless number of possible samples. New samples might show satisfaction percentages of, say, 0.741 and even 0.809. What we need is a tool for assessing whether 0.843 based on a sample of 500 cases is significantly greater than 0.80 based on 200 000. Assume that we had conducted 100 random samples each of size $n = 500$. How many would show a satisfaction ratio higher than 0.8? Moreover, how should we react upon the findings? If satisfaction is significantly higher than 0.8, we might drop a planned, expensive promotional campaign. In case it is significantly less than 0.80, we would launch the campaign, ask consultants and sellers to visit less satisfied customers, and so on.

2 hypothesis testing related to differences – parametric tests

HYPOTHESIS TESTING: TESTING A HYPOTHESIS ABOUT THE MEAN (LARGE SAMPLE)

In the first decades of the twentieth century, theorists within the field of scientific research established a formalized procedure. It became common to develop a hypothesis or rather two mutually exclusive hypotheses. Two competing hypotheses are launched, out of which only one represents the true state of nature. The hypothesis under test is normally called the *null hypothesis* and is denoted H_0 while the alternative hypothesis is named H_A . Usually, what we wish to reject is H_0 .

An example

H_0 : customer satisfaction is less than or equal to 0.8

H_A : customer satisfaction is greater than 0.8

Basically, there are two ways to assess if 0.843 is significantly greater than 0.8 (assuming that the data are normally distributed):

1. We look at the probability value assigned to the empirical measurement. If the probability of empirically observing 0.843 – provided that the true but unobservable value (called μ) is ≤ 0.80 – is less than 0.05 (5 out of 100), then we reject H_0 .
2. Another option would be to inspect the length of the so-called *confidence interval*: If the confidence interval associated with 0.843 does not include 0.8, say, that it runs from 0.811 to 0.875, then we reject H_0 .

Today it has become common standard for statistical textbooks and for scientific publications to use hypothesis tests based on probability values and confidence intervals. Almost all statistical software (SAS, SPSS, Minitab, etc.) provide a number of quantitative tests.

It should be noted, though, that terms like *hypothesis test*, *probability value*, and *confidence intervals* are of rather recent origin.

The use of probability values was first introduced by the eminent statistician R. A. Fisher (1890–1962). He personally developed most of the significance testing methods now in use (Salsburg, 2001, p. 98). The idea of testing a hypothesis (H_0) against an alternative hypothesis (H_A)

was suggested originally by the Polish mathematician Jerzy Neyman (1894–1981) in collaboration with Karl Pearson (1857–1936). Research scientists at that time regarded a hypothesis as either false or true.

In 1934, Karl R. Popper (1902–1994) published *The Logic of Scientific Discovery* in which he argued that scientific statements should be *refutable* or *falsifiable*. Statements or arguments that are vague, imprecise, or qualitative cannot be controlled by way of a statistical test. Such statements are to be characterized as unscientific.

According to Popper there is a need to draw a line in the sand between science and nonscience (metaphysics). He named it *the problem of demarcation*. Popper also argued that even though all empirical evidence appears to support a hypothesis, we can never be 100% sure that it is correct or true. At any point of time, new evidence may refute H_0 and instead support H_1 .

Most probably inspired by Popper's falsification concept, research scientists began to develop a more focused approach: a hypothesis (H_0) is either rejected or, alternatively, the effort to reject the hypothesis by way of an alternative hypothesis (H_A) has so far been unsuccessful. Consequently, the null hypothesis is accepted until new empirical evidence leads to its falsification.

One use of tests of significance has been very common. If investigators claim that method A is superior to method B for some purposes, the claim is unlikely to be accepted by their peers in scientific journals unless they can present results of a comparative study that show A superior to B in a test of significance at the 5 or 1% level. This practice has been beneficial in preventing false claims from spreading and in saving the time and experience needed to show later that the claims were false, though the practice presumably has discouraged some work that would have been fruitful.

An empirical test of a hypothesis consists of several successive steps:

1. Develop the hypotheses. Explicitly formulate the null and the alternative hypotheses.
2. Specify the level of significance (5%, 1%).
3. Determine the direction of the test (one sided vs. two sided).

4. Select an appropriate statistical test (Z -test, t -test) and a sampling distribution (normal distribution, t -distribution, etc.).
5. Collect the sample data.
6. Estimate the value of the test statistic and/or the width of the confidence interval.
7. State the statistical conclusion.
8. Carry out the managerial decision.

Today, many consumer organizations perform checks of the truthfulness of information on a product package. Is the producer's claim regarding volume, fat percentage, nutritional content, and so on factually correct? (see OPPORTUNITIES AND CHALLENGES IN SOCIAL MARKETING).

Assume that a consumer organization suspects a producer of soft drink of underfilling its bottles. The package label states that a bottle contains 0.500 l.

- *Step 1:* First, two hypotheses are established:
 - H_0 = on average (as represented by the mean) a bottle contains 0.500 l or more
 - H_A = on average a bottle contains less than 0.500 l.
- *Step 2:* The level of significance is set to 0.05. In other words, the accepted error rate is 5%. If we conducted the test 100 times we would accept no more than 5 occurrences where H_0 is rejected given that it is, indeed, true. In the remaining 95 cases rejecting H_0 would be the correct decision because H_0 is false.
- *Step 3:* In the present case, the test is *unidirectional*. The consumer organization is only interested in testing whether the consumers get less soft drink than stated on the label. Provided that the producer, on average, puts more than 0.5 l in the soft drink, it is his problem. Providing more value than promised is not illegal.
- *Step 4:* The test to be used is a so-called Z -test according to the normal distribution (see below).
- *Step 5:* The consumer organization collects a sample of 30 soft-drink bottles from different retail outlets. Next, the content of each of the bottles is carefully measured. Table 1 shows the results. In the present case, the sample

mean, \bar{x} , is 0.485 and the sample standard deviation, s , is 0.028. Since the sample size is ≥ 30 the central limit theorem applies, implying that the test can be carried out using the standard Z -test according to the normal distribution. Note that in statistical tests a sample is regarded “large” whenever $n \geq 30$.

- *Step 6:* The Z -test for a single mean is

$$Z = \frac{\bar{x} - \mu}{\left(\frac{\sigma}{\sqrt{n}}\right)} \quad (1)$$

In the present case, μ – the population mean – is set at 0.500, $\bar{x} = 0.485$, $n = 30$, and the population standard deviation σ is estimated by the sample standard deviation, $s = 0.028$. Thus,

$$Z = \frac{0.485 - 0.500}{\left(\frac{0.028}{\sqrt{30}}\right)} = -2.934 \quad (2)$$

- *Step 7:* To assess whether this value is statistically significant, one needs to inspect the standard normal distribution (see Figure 1). The threshold level for the 0.95 or 95% one-sided test is -1.645 . The Greek letter α refers to the relative size of the area under the normal distribution *to the left of* -1.645 . This implies that only in 5% of cases we would expect the z -value to be less than -1.645 . Since our empirical value is -2.934 , we reject H_0 and accept H_A implying that the mean bottle content is significantly less than 0.500 l (the actual probability value is 0.0016). The precise probability corresponds to somewhere between 1 and 2 cases out of 1000.
- *Step 8:* Conclusion: The consumer organization has statistical justification for taking legal action against the producer for underfilling its soft-drink bottles.

ONE- AND TWO-TAILED TESTS

In the above example, the statistical test is carried out as a one-tailed or unidirectional test. The consumer organization's only concern is that the consumer gets no less than stated

Figure 1 One-sided test.

Table 1 Exact content of 30 test bottles.

| Bottle Number | Liter | Bottle Number | Liter | Bottle Number | Liter |
|---------------|-------|---------------|-------|---------------|-------|
| 01 | 0.492 | 11 | 0.498 | 21 | 0.475 |
| 02 | 0.487 | 12 | 0.497 | 22 | 0.526 |
| 03 | 0.479 | 13 | 0.477 | 23 | 0.503 |
| 04 | 0.491 | 14 | 0.481 | 24 | 0.447 |
| 05 | 0.519 | 15 | 0.507 | 25 | 0.450 |
| 06 | 0.476 | 16 | 0.499 | 26 | 0.474 |
| 07 | 0.480 | 17 | 0.499 | 27 | 0.499 |
| 08 | 0.468 | 18 | 0.442 | 28 | 0.546 |
| 09 | 0.532 | 19 | 0.448 | 29 | 0.469 |
| 10 | 0.491 | 20 | 0.418 | 30 | 0.476 |

on the label, that is, *at least* 0.5001. A closer look at Table 1 reveals that in 6 out of the 30 cases the volume actually exceeds 0.5001. From a producer's perspective, delivering more volume than promised may result in losses or at least in less profits than planned. Therefore, a decent management should strive for getting as close to the 0.5001 target value as possible. Delivering less than 0.5001 is regarded unfair to the consumer and may result in consumer complaints, while delivering more than 0.5001 is regarded as unfavorable to management since it decreases company profits.

In such a case, the statistical test is a two-tailed test. The computations are the same, but the implications from the test differ somewhat.

Assure that the above test value of 2.934 refers to a two-sided test (Figure 2 shows a two-sided

test to be discussed below). In this case, we would reject H_0 either if (i) the observed z -value is less than -1.96 or (ii) if it is greater than $+1.96$. Otherwise, that is, if $-1.96 < z < +1.96$, we would accept H_0 . Since the test is two sided, the probability of observing -2.934 is $2 \times (0.0016) = 0.0032$.

In the example of Table 1, the mean value of 0.485 is regarded *a point estimate*. If we assure that we are conducting a new test of $n = 30$, the mean would most probably not be 0.485 but rather 0.483, 0.491, or some other value.

Therefore, it is preferable to look at the *confidence interval* surrounding the point estimate. A 95% confidence interval represents a range. Given 100 measures we would expect the point estimate to fall within this span in 95 of the cases.

In the present case the confidence interval is

$$\begin{aligned}\bar{x} \pm z_{\alpha/2} \left(\frac{s}{\sqrt{n}} \right) &= 0.485 \pm 1.96 \left(\frac{0.028}{\sqrt{30}} \right) \\ &= [0.475; 0.495] \quad (3)\end{aligned}$$

In other words, there is a 95% probability that the true but unknown population parameter of the mean will be somewhere between 0.475 and 0.4951. It is noticed that even the upper bound (0.495) does not overlap with 0.500.

Suppose that we are very conservative, and that the test level of 5% error is regarded too liberal. Instead, we only accept a 0.1% level of error. In this case, the confidence interval

Figure 2 Two-sided test.

Table 2 Decisional dilemmas involved in hypothesis testing.

| | | State of Nature | |
|----------|-------------------------------|--------------------|--------------------|
| | | H_0 True | H_A True |
| Decision | Accept (fail to reject) H_0 | Correct conclusion | Type II error |
| | Reject H_0 | Type I error | Correct conclusion |

becomes

$$\begin{aligned}\bar{x} \pm z_{\alpha/2} \left(\frac{s}{\sqrt{n}} \right) &= 0.485 \pm 3.09 \left(\frac{0.028}{\sqrt{30}} \right) \\ &= [0.469; 0.501]\end{aligned}\tag{4}$$

In this case, the upper bound of the confidence interval accurately exceeds 0.500. Therefore, if we want to be very sure about not falsely suing the company – that is, only accepting an error in 1 out of 1000 cases – we cannot rule out that the producer of soft drink is systematically *not* underfilling its bottles.

Notice that as we lower the probability of committing an error (increasing the error rate from 0.05 to 0.001) the width of the confidence interval increases.

Typical examples of two-sided tests are a candy bar or a soft drink containing a certain degree of sugar. If it contains too little sugar it

tastes bitter and if it contains too much sugar it tastes too sweet. Likewise, most consumers prefer a specific amount of alcohol in red wine (13–14%). Also, in industrial production processes and when producing medical drugs well-specified two-sided tolerance levels are appropriate. Otherwise, the product quality suffers or the side effects increase beyond acceptable levels.

TYPE I AND TYPE II ERRORS

Whenever testing a statistical hypothesis, one faces two decisional dilemmas: (i) the risk of rejecting something that is actually true (called a *type I error*) or (ii) the risk of accepting something that is not true or that is false (*type II error*) (see Table 2). Alpha (α) or the level of significance is the probability of committing a type I error, whereas the corresponding probability of committing a type II error is called

6 hypothesis testing related to differences – parametric tests

beta (β). There exists an inverse relationship between α and β . For a given sample size, β increases as α decreases. Stated differently, the more confident we want to be that our decision to reject H_0 is correct, the bigger is the chance that we accept a H_0 that is wrong. As we showed in the example with the soft-drink producer decreasing α from 0.05 to 0.001 implies that we fail to reject H_0 . However, since our sample consisted of only 30 cases it is probable that new samples of $n = 30$ or a sample of $n = 300$ or 3000 will result in empirical means different from 0.485. Presuming that the soft drink example consist of 300 cases instead of 30, and supposing that the mean (0.485) and the standard deviation (0.028) is unchanged, the width of the 95% confidence interval narrows to [0.482; 0.488]. In this case, even the 99.9% confidence interval [0.480; 0.490] does not include 0.500, and thus we would definitely reject H_0 and recommend that legal action be taken against the producer for underfilling its bottles.

Generally, the probability of making a type II error increases as the value of the true population mean (estimated by the sample mean) is close to the H_0 value. Conversely, if the true population mean is far from H_0 the probability of committing a type II error is low.

Every day, we need to make decisions involving the risk of committing type I and type II errors. In the majority of cases, the consequences of the two error types are limited. Situations exist though, where making type I and type II errors are fatal. Imagine an airline pilot flying in darkness over mountains. Suddenly he gets a message from the Terrain Awareness and Warning System (“Terrain, Terrain”) indicating that the plane is close to impact. At the same time, the plane’s altimeter indicates that he is flying at an altitude of 6000 m. Which information should he believe? If he decides to take the warning seriously he would have to climb very quickly and pressure the airplane to its limits, thereby running the risk of its getting out of control and a part of the tail or even the fuselage breaking apart. On the other hand, if he should decide to ignore the warning system – and if it is correct – the plane will crash into the mountain within seconds.

Let us use the juridical system to illustrate the problem. In a criminal case, the accused

is regarded as not guilty until the opposite is proved. In other words, H_0 = the accused is *not* guilty and H_A = the accused is guilty.

In this case, a type I error corresponds to a situation where the accused is innocent (H_0 – the attorney’s claim is true) but where the person, nevertheless, is convicted and sent to prison (or even execution) for the crime. A type II error would correspond to the opposite situation: the accused is indeed guilty (H_A is true) but is released due to lack of evidence.

According to most lawyers, committing a type I error is worse than causing a type II error. In recent decades, the increasing use of DNA tests has helped in revealing and subsequently reversing a lot of type I and type II errors carried out by courts prior to the appearance of DNA tests.

Management also has to make decisions involving type I and type II errors. Consider a company that is about to launch a new product. Consequently, two hypotheses are established:

H_0 = the new product will not be profitable

H_A = the new product will be profitable.

Notice that we want to *reject* H_0 , that is, we would like the new product to be successful.

If management makes the decision to launch the product (accept H_A) but the product turns out to be a failure, (H_0 being true) a type I error has been committed. Usually, this is called *mismarketing*. Alternatively, if management decides not to launch (accept H_0) and it turns out that there is indeed a market (say, that a competitor markets a similar product that proves successful), this would be an example of a type II error. In most situations, a type I error (mismarketing) is regarded as more serious than a type II error (lost opportunity).

SAMPLE SIZE AND TEST STATISTICS: SMALL SAMPLE TEST OF THE MEAN

Up to now we have assumed that empirical tests were based on “large samples,” implying that the sample size is at least 30 (the rationale of the minimum size of 30 is caused by the so-called *central limit theorem*). However, sometimes samples are small. In such cases, we must assume that the underlying population is normally distributed.

Suppose that in the example about under-filling of bottles, the available data consist of only the 10 observations in the second row of Table 1 (Bottles 1–10). In this situation, calculations are carried out in accordance with a t -test:

$$t = \frac{\bar{x} - \mu}{\left(\frac{s}{\sqrt{n}}\right)} = \frac{0.492 - 0.500}{\left(\frac{0.020}{\sqrt{10}}\right)} = -1.26 \quad (5)$$

The t -distribution resembles the standard normal distribution but differs somewhat in shape. And unlike the normal distribution, the t -distribution is characterized by a degree-of-freedom parameter. In the present case, the probability value associated to -1.26 with $n - 1 = 9$ degrees of freedom (assuming a two-tailed test) is 0.24 implying nonsignificance. Therefore, we cannot say that the company is underfilling its bottles. The same conclusion can be illustrated by computing the confidence interval around the mean, using a t -test with two tails and selecting an alpha level of 0.05.

$$\begin{aligned} \bar{x} \pm t_{\alpha/2} \times \frac{s}{\sqrt{n}} &= 0.492 \pm 2.28 \times \left(\frac{0.020}{\sqrt{10}}\right) \\ &= 0.492 \pm 0.014 \\ &\text{or } [0.478; 0.506] \end{aligned} \quad (6)$$

We notice that the upper bound of 0.506 overlaps the threshold level of 0.500. Thus we cannot be 95% sure that the company is underfilling its bottles.

TEST OF A POPULATION PROPORTION: LARGE SAMPLE

When dealing with a population proportion, computation of statistical significance and confidence intervals differ somewhat from when dealing with a population mean. Presume that the management of a retail chain specialized in fair trade clothes wants to find out if it has significantly more female customers than male customers. Management has decided that if the proportion of female customers is significantly bigger than the proportion of males, it will launch an advertising campaign in a regional magazine for women. Thus it conducts 400 interviews, with respondents randomly selected from the

company's customer database. It turns out that 229 of the respondents are females.

Formally the hypotheses are $H_0: p \leq 0.50$ versus $H_A: p > 0.50$ (p is called the *population proportion*).

The appropriate test statistic is

$$z = \frac{\bar{p} - p_0}{\sqrt{\frac{p_0(1 - p_0)}{n}}} \quad (7)$$

It is a condition that $n \times p$ as well as $n \times (1 - p) \geq 5$, where \bar{p} is the sample proportion and p_0 is population proportion.

In the present case, $n \times p = 400 \times \left(\frac{229}{400}\right) = 229$ and $n \times (1 - p) = 400 \times \left(1 - \left(\frac{229}{400}\right)\right) = 171$. Since $229 > 5$ and $171 > 5$ we can use the z -test.

$$z = \frac{\left(\frac{229}{400}\right) - 0.50}{\sqrt{\frac{0.50(1 - 0.50)}{400}}} = \frac{0.0725}{0.025} = 2.90 \quad (8)$$

The related two-sided confidence interval is computed thus (assuming a 95% confidence interval and a two-tailed test):

$$\bar{p} \pm z_{.025} \sqrt{\frac{\bar{p} \times (1 - \bar{p})}{n - 1}} \quad (9)$$

Here

$$\begin{aligned} \left(\frac{229}{400}\right) \pm 1.96 \times \sqrt{\frac{\left(\frac{229}{400}\right) \times \left(1 - \left[\frac{229}{400}\right]\right)}{400 - 1}} \\ = 0.5725 \pm 0.0486 \\ \text{or } [0.524; 0.621] \end{aligned} \quad (10)$$

Since 2.90 exceeds 1.96 (and as the confidence interval does not include 0.5) we conclude that the proportion of female customers significantly exceeds that of male customers (the associated probability value of 2.90 is 0.998 (or $1 - 0.002$) (see Figure 2). On the basis of the test, we make the conclusion that H_0 is rejected: the retail store has significantly more female than male customers. Consequently, it is recommended that management advertises in magazines for women.

Table 3 Age of two samples of customers.

| Downtown Supermarket | | | | | Suburban Supermarket | | | | |
|-------------------------|----|----|----|----|-------------------------|----|----|----|--|
| 28 | 41 | 43 | 42 | 41 | 36 | 42 | 35 | 54 | |
| 44 | 35 | 44 | 58 | 36 | 38 | 46 | 37 | 23 | |
| 39 | 41 | 45 | 48 | 28 | 36 | 22 | 38 | | |

| 20 | 45 | 34 | | 57 | 35 | 38 | 29 | | |
| 39 | 49 | 53 | | 39 | 13 | 39 | 16 | | |
| 34 | 45 | 41 | | 14 | 29 | 40 | 35 | | |
| 37 | 41 | 46 | | 50 | 41 | 34 | 35 | | |
| 38 | 43 | 34 | | 40 | 35 | 39 | 37 | | |
| 37 | 21 | 22 | | 33 | 43 | 44 | 36 | | |

TEST OF A POPULATION PROPORTION:
SMALL SAMPLE

Tests for small samples concerning a population proportion are rarely used since the sample distribution follows a binomial distribution and therefore a normal approximation strictly does not apply. Several tests have been suggested, though. One such test is known as *Wilson's confidence interval* (Henderson and Meyer, 2001). Assume that we have conducted a small taste test among 20 persons ($n = 20$) and that 6 of them prefer the taste of our product to that of the competitor's product ($k = 6$). The $100(1 - \alpha)\%$ Wilson confidence interval is

$$\frac{k + \frac{z_{\alpha/2}^2}{2}}{n + z_{\alpha/2}^2} \pm z_{\alpha/2} \times \sqrt{\frac{n \times \bar{p} \times (1 - \bar{p}) + \frac{z_{\alpha/2}^2}{4}}{(n + z_{\alpha/2}^2)^2}} \quad (11)$$

In the present example – assuming a 95% two-sided test and that \bar{p} is $6/20 = 0.3$ – we have

$$\begin{aligned} & \frac{6 + \frac{(1.96)^2}{2}}{20 + (1.96)^2} \pm 1.96 \\ & \times \sqrt{\frac{20 \times 0.30 \times (1 - 0.70) + \frac{(1.96)^2}{4}}{(20 + 1.96)^2}} \\ & = 0.33 \pm 0.20 \text{ or } [0.13; 0.53] \end{aligned} \quad (12)$$

Notice that 0.33 differs somewhat from \bar{p} (0.30). Crow (1956) has developed tables of 90, 95, and 99% population proportion confidence intervals for all values of k for $n = 1-30$ using a Lagrangian interpolation. With $k = 6$, $n = 20$, and a 95% interval, the width of the interval becomes $[0.14; 0.53]$, which comes very close to the Wilson estimate. Other publications addressing the small sample population proportion problem are Elston and Forthofer (1977) and Westfall (1985).

TEST OF DIFFERENCE BETWEEN POPULATION
MEANS: TWO LARGE SAMPLES

Up to now, all tests have been based on one sample where estimates of means and proportions have been tested against a hypothesized value (H_0). However, sometimes we are interested in comparing differences in means and proportions emanating from two independent samples. In the following, we show how this is done.

We begin with a test of difference between means assuming two big independent samples.

A retail chain is operating two supermarkets in the same city. One of the supermarkets is situated downtown, whereas the other one is in a suburban shopping center. Management is interested in figuring out whether the age of the two supermarkets' customers differs. If there is a significant difference in mean age between the customer bases of the two supermarkets, management might consider varying the supply of certain products between the two stores. So far the supply has been identical. The management makes a questionnaire and interviews a sample of customers at each supermarket (one of the questions concerns age). Table 3 shows the dataset and Table 4 displays the sample statistics.

We notice that the mean age of the downtown sample is higher than that of the suburban

Table 4 Sample statistics for Table 2 data.

| Store | Sample Size | Mean Age | Standard Deviation |
|----------|----------------|---------------------|-----------------------|
| Downtown | $n_1 = 34$ | $\bar{x}_1 = 40.44$ | $S_1 = 8.93$ |
| Suburban | $n_2 = 42$ | $\bar{x}_2 = 35.79$ | $S_2 = 9.54$ |

sample. But is the difference statistically significant? This can be estimated either by way of a z -test or by way of an interval estimate between the two means. The following test assumes that both samples are of size $n \geq 30$ and that σ_1 and σ_2 can be estimated by s_1 and s_2 .

First, let us look at the z -statistic

$$z = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}} \quad (13)$$

In the present case, we have

$$z = \frac{40.44 - 35.79}{\sqrt{\frac{8.93^2}{34} + \frac{9.54^2}{42}}} = 2.19 \quad (14)$$

The related probability value is 0.014 implying that we reject the hypothesis that there is no age difference between downtown and suburban customers.

The corresponding interval is estimated as

$$\bar{x}_1 - \bar{x}_2 \pm z_{\alpha/2} \times \sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}} \quad (15)$$

where $1 - \alpha$ is the confidence coefficient.

Assuming an α test level of 0.05 the interval becomes

$$\begin{aligned} 40.44 - 35.79 \pm 1.96 \times \sqrt{\frac{8.93^2}{34} + \frac{9.54^2}{42}} \\ = 4.65 \pm 4.16 \text{ or } [0.49; 8.81] \end{aligned} \quad (16)$$

We conclude that at a 95% level of confidence the margin of error is 4.16 years and the interval estimate of the difference between the mean ages of the customers of the two supermarkets is 0.49–8.81 years. On the basis of the dataset, it can be concluded that downtown customers are somewhat older than suburban customers.

However, the two samples are not of substantial size and thus very sensitive to small changes in the data. For instance, if the oldest person (age 58) in the downtown sample had instead been shopping at the suburban supermarket while the youngest person (age 13) in the suburban sample had visited the downtown

store, then the confidence interval would change from [0.49; 8.81] to [−2.05; 6.55]. In that case, the lower bound of the confidence interval becomes negative implying that we cannot rule out (on the 95% level) that the mean age of the downtown shoppers is indeed *higher* than that of the suburban shoppers. We also notice that four of the suburban shoppers are teenagers. Is this a small group of school children who coincidentally dropped around and only bought one candy bar or a coke each? Most probably they are atypical shoppers. However, removing them from the computations would totally change the computations (the interval would be [−1.27; 6.25]). To sum up, it is strongly recommended that management collects more interviews so that it can base its decision on statistical estimates that are less sensitive to a few *influential observations* or *outliers*.

TEST OF DIFFERENCE BETWEEN MEANS: TWO SMALL SAMPLES

In most cases, empirical samples conducted by or for companies consist of several hundred or even several thousand cases. However, as mentioned earlier, it may happen that the universe is limited. Many industrial companies have only a few hundred or so customers and, nevertheless, they may be interested in analyzing their customers' purchase behavior. If the number of cases sampled is less than 30 we cannot conduct a test like the one illustrated in the previous section.

First, we make the assumption that both populations have a normal distribution. Second, we presume that the population variances are equal, that is, $\sigma^2 = \sigma_1^2 = \sigma_2^2$. Third, since the variances normally are unknown, we assume that s , the standard deviation, can serve as a valid substitute for σ .

This being the case we can establish a pooled variance estimator:

$$s_{\text{pooled}}^2 = \frac{(n_1 - 1) \times s_1^2 + (n_2 - 1) \times s_2^2}{n_1 + n_2 - 2} \quad (17)$$

the t -test with $n_1 + n_2 - 2$ degrees of freedom becomes

$$t_{\alpha/2} = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{s_{\text{pooled}} \times \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}} \quad (18)$$

10 hypothesis testing related to differences – parametric tests

Table 5 Sales (in 000 EUR) to customers.

| Germany | France |
|---------|--------|
| 982 | 842 |
| 1205 | 905 |
| 1031 | 1044 |
| 975 | 732 |
| 833 | 746 |
| 921 | 955 |
| 1114 | 1031 |
| 1082 | 958 |
| 1227 | 1089 |
| 1086 | 887 |
| 997 | |
| 701 | |

The corresponding confidence interval is

$$\bar{x}_1 - \bar{x}_2 \pm t_{\alpha/2} \times s_{\bar{x}_1 - \bar{x}_2} \quad (19)$$

Table 5 displays sales to a sample of an original equipment manufacturer company's industrial customers in Germany and France and Table 6 shows the sample statistics. Suppose that management would like to assess if the difference in mean between German and French sales is statistically significant.

First, we estimate the pooled variance estimator:

$$\begin{aligned} s_{\text{pooled}}^2 &= \frac{(12 - 1) \times 148.98^2 + (10 - 1) \times 121.08^2}{12 + 10 - 2} \\ &= 18,804 \end{aligned} \quad (20)$$

Next, the difference in mean is tested by way of a t -test:

$$\begin{aligned} t_{\alpha/2} &= \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{s_{\text{pooled}}^2 \times \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}}; \\ \text{here : } &\frac{1012.83 - 918.90}{\sqrt{18,804 \times \left(\frac{1}{12} + \frac{1}{10} \right)}} \\ &= 1.600 \end{aligned} \quad (21)$$

Table 6 Sample statistics for Table 5 data.

| Country | Sample Size | Mean Sale | Standard Deviation |
|---------|-------------|-----------------------|--------------------|
| Germany | $n_1 = 12$ | $\bar{x}_1 = 1012.83$ | $S_1 = 148.98$ |
| France | $n_2 = 10$ | $\bar{x}_2 = 918.90$ | $S_2 = 121.08$ |

The associated probability value with $n_1 + n_2 - 2$ degrees of freedom is 0.125 – a value that is not statistically significant.

The corresponding confidence interval (a t -test with 20 degrees of freedom and assuming a 95% confidence level) becomes

$$\begin{aligned} &1012.83 - 918.90 \pm 2.09 \\ &\times \sqrt{18,804 \times \left(\frac{1}{12} + \frac{1}{10} \right)} = 93.93 \\ &\pm 122.71 \text{ or } [-28.78; 216.64] \end{aligned} \quad (22)$$

Although the mean sale to German customers exceeds that to French customers, the difference is not statistically significant. Since the lower bound of the confidence interval is negative, we cannot rule out that the sale to French customers is actually greater than that to Germans.

TEST OF DIFFERENCE BETWEEN POPULATION PROPORTIONS: TWO LARGE SAMPLES

In certain situations, management may want to compare two population proportions. We assume that the two samples are independent and that $n_1 \times p_1$, $n_1 \times (1 - p_1)$, $n_2 \times p_2$, and $n_2 \times (1 - p_2)$ are all ≥ 5 . If these conditions are fulfilled, we can compute a z -value.

However, to begin with, we need two alternating hypotheses:

$$H_0 : p_1 - p_2 = 0 \text{ or}$$

$$H_1 : p_1 - p_2 \neq 0.$$

First, assume that

$$\bar{p} = \frac{\bar{p}_1 + \bar{p}_2}{n_1 + n_2} \quad (23)$$

If this applies, the appropriate test statistics becomes

$$z = \frac{\bar{p}_1 - \bar{p}_2}{\sqrt{\bar{p} \times (1 - \bar{p}) \times \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}} \quad (24)$$

The interval estimate for the difference between the population proportions is computed thus:

$$(\bar{p}_1 - \bar{p}_2) \pm z_{\alpha/2} \times \sqrt{\frac{\bar{p}_1 \times (1 - \bar{p}_1)}{n_1 - 1} + \frac{\bar{p}_2 \times (1 - \bar{p}_2)}{n_2 - 1}} \quad (25)$$

Suppose that a new hair shampoo has been launched in two regions in opposite areas of a country. The two regions are regarded similar with respect to size of population and to sociodemographic characteristics. During a six-week period, the product is heavily advertised and the same amount is spent on the campaign in both markets. However, in the upper region all advertising money is spent on TV, whereas the money in the lower region is spent on a mix of TV, radio, newspaper, magazines, and Internet (Facebook, etc.).

Immediately after the end of the campaign, management hires a market research agency to carry out 1000 representative interviews in both regions asking respondents if they have seen and/or heard anything about the campaign. The results are as follows:

Upper region: $629/1000 = 0.629$

Lower region: $796/1000 = 0.796$

$$\bar{p} = \frac{629 + 796}{1000 + 1000} = 0.713 \quad (26)$$

$$\begin{aligned} z_{0.025} &= \frac{0.629 - 0.796}{\sqrt{0.713 \times 0.287 \times \left(\frac{1}{1000} + \frac{1}{1000}\right)}} \\ &= -8.255 \end{aligned} \quad (27)$$

The probability value of this estimate is less than 0.000. Therefore we reject H_0 .

Selecting a 95% interval we get

$$\begin{aligned} & (0.629 - 0.796) \pm 1.96 \\ & \times \sqrt{\frac{(0.629 \times 0.371)}{1000 - 1} + \frac{(0.796 \times 0.204)}{1000 - 1}} \\ & = -0.167 \pm 0.039 \\ & \text{or } [-0.206; -0.128] \end{aligned} \quad (28)$$

The interval implies that we can be 95% confident that the proportion of residents in the upper

region who have become aware of the product is between 13 and 21% less than the proportion of residents in the lower region. Thus we have considerable evidence that the multimedia strategy that was being used in the lower region has been more successful with regard to generating attention than the single-media campaign of the upper region.

TEST OF DIFFERENCE BETWEEN TWO POPULATION PROPORTIONS: TWO SMALL SAMPLES

In the previous section, it was assumed that the two samples were big. Comparing two proportions where one or both samples are smaller than 30 rarely makes sense.

Nevertheless, a formula for the confidence interval has been developed for such situations. Agresti and Caffo (2000) suggest the following crude normal approximation:

$$(\bar{p}_1 - \bar{p}_2) \pm z_{\alpha/2} \times \sqrt{\frac{\bar{p}_1 \times (1 - \bar{p}_1)}{n_1 + 3} + \frac{\bar{p}_2 \times (1 - \bar{p}_2)}{n_2 + 3}} \quad (29)$$

According to Agresti and Caffo (2000) this test appears to perform quite well in many situations.

Assume that we have been interviewing 25 persons in the upper region out of which 16 have heard of the new product while 12 out of 15 in the lower region report knowledge of the new product. In this case, we have

$$\begin{aligned} & (0.640 - 0.800) \pm 1.96 \\ & \times \sqrt{\frac{(0.640 \times 0.360)}{25 + 3} + \frac{(0.800 \times 0.200)}{15 + 3}} \\ & = -0.160 \pm 0.131 \\ & \text{or } [-0.291; -0.029] \end{aligned} \quad (30)$$

We notice that the confidence interval based on the small sample is longer than that of the big sample. However, the lower-region campaign is found to be more successful than the upper-region campaign.

12 hypothesis testing related to differences – parametric tests

TEST OF DIFFERENCE BETWEEN TWO
MEANS: MATCHED SAMPLES

Up to now we have assumed that the two samples are unrelated or independent. Sometimes, it is of interest to take repeated measurements from the same individuals. In a blind test, a person may be asked to taste several soft drinks with different flavors and afterward the person is asked which one is preferred by way of a rating scale.

Another example of a related sample is a “before and after measurement.” Presume that a sample of frequent customers of a company is asked to rate one of its well-known brands on a 0–100 temperature scale (the higher the better) according to purchase intention. Afterward they are exposed to a 2-min advertisement of the brand and subsequently they are asked to rate the brand once again. Table 7 shows an example of such a before-and-after rating.

The appropriate test is

$$t = \frac{\bar{d}}{\sqrt{\frac{1}{n \times (n-1)} \times \sum_{i=1}^n (d_i - \bar{d})^2}}; \text{ here we have:}$$
$$\frac{3.85}{\sqrt{\frac{1}{20 \times 19} \times 354.55}} = 3.986 \quad (31)$$

The test value is t -distributed with $n - 1$ degrees of freedom. In the example, the 95% two-sided test with 19 degrees of freedom has a p -value of 0.00079. In other words, the probability that the two related samples are equal is less than 1 : 1000. Clearly, exposing persons to the advertisement has increased the brand’s preference rating.

Since $t_{0.05/2;19} = 2.093$ it follows that the related confidence interval is

$$\bar{d} \pm t_{\alpha/2;n-1} \times \frac{s_d}{\sqrt{n}}; \text{ here } 3.85 \pm 2.093$$
$$\times \frac{4.32}{\sqrt{20}} \text{ or } [1.83; 5.88] \quad (32)$$

We notice that the lower bound of the 95% confidence interval does not include 0.00. So, on the 95% level we reject the possibility that being exposed to the advertisement has lowered the purchase intention.

Table 7 Two related samples: before and after measurement.

| Person | Before | After | Difference | $(Diff_i - Diff_{mean})^2$ |
|--------|--------|-------|----------------------|----------------------------|
| 1 | 65 | 72 | 7 | 9.92 |
| 2 | 59 | 60 | 1 | 8.12 |
| 3 | 78 | 78 | 0 | 14.82 |
| 4 | 67 | 66 | −1 | 23.52 |

| | | | Diff _{mean} | 3.85 |
| | | | Diff _{std} | 4.32 |

TESTING FOR THE EQUALITY OF TWO
POPULATION VARIANCES

Sometimes we are interested in differences in the *variance* of samples rather than in differences of means.

Assume a producer who has two production facilities for fabrication of red wine. Typically, a red wine contains around 12.5% of alcohol. The authorities allow for a 1.5% leeway in accuracy of the alcohol level. Government authorities regularly visit producers for taking samples of the alcohol content. If the alcohol content in a sample exceeds 14%, the wine cannot be sold in retail stores or to the catering sector. If the content is lower than 12.5%, the wine can be sold. However, in all probability, wine experts will give the wine unfavorable reviews and sales will decline.

Table 8 Alcohol content of wine.

| Facility 1 | Facility 2 |
|------------------------------------|------------|
| 13.29 | 12.16 |
| 11.64 | 12.41 |
| 13.79 | 12.45 |
| 12.44 | 12.27 |
| 12.61 | 12.45 |
| 12.82 | 12.62 |
| 11.75 | 12.44 |
| 12.30 | 12.88 |
| 11.97 | 12.05 |
| 12.22 | 12.46 |
| 12.46 | |
| 13.33 | |
| <hr/> | |
| $\bar{x}_1 = 12.55, S_1^2 = 0.430$ | |
| $\bar{x}_2 = 12.42, S_2^2 = 0.054$ | |

Therefore management considers it very important to produce a wine that gets as close as possible to the 12.5% target. Thus it collects a sample of bottles from the two production facilities and gets them analyzed by a laboratory. Table 8 displays the results.

The appropriate test for testing the equality of variances is

$$F = \frac{s_1^2}{s_2^2}; \text{ here } F = \frac{0.430}{0.054} = 8.0 \quad (33)$$

The degrees of freedom are f_1 (numerator) = $n_1 - 1 = 12 - 1 = 11$, and f_2 (denominator) = $n_2 - 1 = 10 - 1 = 9$.

The probability value of an F -value with 11 and 9 degrees of freedom is 0.002. Clearly, the variance of the wine percentage differs. There seems to be little doubt that the variance in alcohol percentage varies more in facility 1 than in facility 2, in spite of the fact that the mean percentage is nearly the same. It is recommended that management aims at providing a more stable production of wine in facility 1.

Hint: In the F -ratio always put the biggest variance in the nominator (as was done above). Otherwise, the test value would become $1/8 = 0.125$. The F -distribution is nonnegative and asymmetric implying that its peak usually is

found left to the “center” (in such a case, the distribution is said to be *right skewed*). The F -test has two tails and, consequently, with a value of 0.125, the test would need to be carried out as a lower-tailed test meaning that the *smaller* the test value the smaller the probability. This often causes confusion even for people familiar with statistics. Readers who would like to know more about the F -test and about statistical distributions, in general, are referred to textbooks on business statistics like Anderson, Sweeny, and Williams (2003), Blackwell and Eldredge (2002) or Bowerman and O’Connell (2003).

TEST OF DIFFERENCE BETWEEN TWO MEANS WHEN VARIANCES ARE NOT EQUAL

When computing tests of significance and confidence intervals for the difference between means of two independent samples, it is usually assumed that the two population variances are equal. In such a case, the pooled standard deviation can be used as an estimator of the variance. However, as we have shown in the previous section, variances (as estimated by way of standard deviations) are not always equal.

If variances are not equal and if the sample size is small, the usual test cannot be conducted and a revised test must be employed.

Table 9 displays a small two-sample case where variances are obviously unequal.

Table 9 Measurements of cheese fat percentage.

| | Facility A | Facility B |
|-------|------------|------------|
| | 18 | 24 |
| | 23 | 25 |
| | 28 | 26 |
| | 22 | 25 |
| | 25 | |
| | 17 | |
| | 16 | |
| | 19 | |
| <hr/> | | |
| Mean | 21 | 25 |
| s^2 | 17.71 | 0.67 |

14 hypothesis testing related to differences – parametric tests

In this case, the ordinary t -test is replaced by a revised test statistic:

$$t' = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}} \quad (34)$$

According to Satterthwaite (1946), t' can be estimated by way of an ordinary t -distribution if an approximate number of degrees of freedom is computable.

Assume that

$$v_1 = \frac{s_1^2}{n_1} \text{ and that } v_2 = \frac{s_2^2}{n_2} \quad (35)$$

When comparing the mean of the two samples, we presume that $m_1 = n_1 - 1$ and $m_2 = n_2 - 1$. In this case, the approximate number of degrees of freedom of t' is given by

$$v' = \frac{(v_1 + v_2)^2}{\frac{v_1^2}{m_1} + \frac{v_2^2}{m_2}} \quad (36)$$

then v' is to be rounded *down* to the nearest integer when using the t -distribution. Here we have

$$t' = \frac{21 - 25}{\sqrt{\frac{17.71}{8} + \frac{0.67}{4}}} = 2.592$$

and

$$v' = \frac{\left(\frac{17.71}{8} + \frac{0.67}{4}\right)^2}{\left(\frac{\left(\frac{17.71}{8}\right)^2}{7} + \frac{\left(\frac{0.67}{4}\right)^2}{3}\right)} = 7.99 \quad (37)$$

Since the probability value associated with $t = 2.592$ and 7 degrees of freedom (not 8!) is 0.0358, we reject the hypothesis (H_0) that the fat percentage of the two production facilities is the same. The fat percentage at facility B is higher but the variability across samples is more stable.

Notice that an ordinary t -test based on the Table 9 data with a pooled s^2 computed by

employing formulas (17) and (18) above yields a value of -1.84 with an erroneous 10 degrees of freedom corresponding to a (two-tailed) probability value of 0.10. Thus, using an ordinary t -test we would erroneously accept H_0 . The ordinary t -test tends to give too few significant results when the larger sample has the larger variance (as in our example) and too many when the larger sample has the smaller variance (see Snedecor and Cochran, 1989, pp. 96–99).

MISCELLANEOUS

Hypothesis tests, probability values, and confidence intervals are sensitive to sample size. Therefore the researcher will often need to decide upon an appropriate *sample size* (see STATISTICAL APPROACHES TO DETERMINING SAMPLE SIZES) prior to gathering data. Another problem not addressed here concerns the ratio between size of the sample and of the population. If the population is less than 20 times bigger than the sample (if $n/N > 0.05$), confidence intervals for the mean and the proportion need to be adjusted or multiplied by the *finite population correction factor*, $\sqrt{\frac{N-n}{N}}$.

Notice that as n increases compared to N the correction factor decreases implying that the width of the confidence interval shrinks. Obviously, if $n = N$, that is, if the whole population is sampled (as census offices in some countries do in certain cases), then the correction factor becomes 0 and so does the width of the confidence interval. In such a case, there is no sampling error. Suppose that a company has 500 customers in its database and wants to survey 100. Since $500/100 = 5$, which is less than 20, the confidence intervals must be multiplied by $\sqrt{\frac{500-100}{500}} = 0.894$ (see Bowerman and O'Connell, 2003, pp. 283–286).

All statistical tests discussed in this section involve one or two samples. If one wants to test for the equality of means and more than two independent samples are involved, then the appropriate test is an *analysis of variance* or *ANOVA test* (see ANALYSIS OF VARIANCE AND COVARIANCE).

In case the assumptions underlying parametric tests are violated (homogeneity of variance/covariance, normality, etc.) researchers

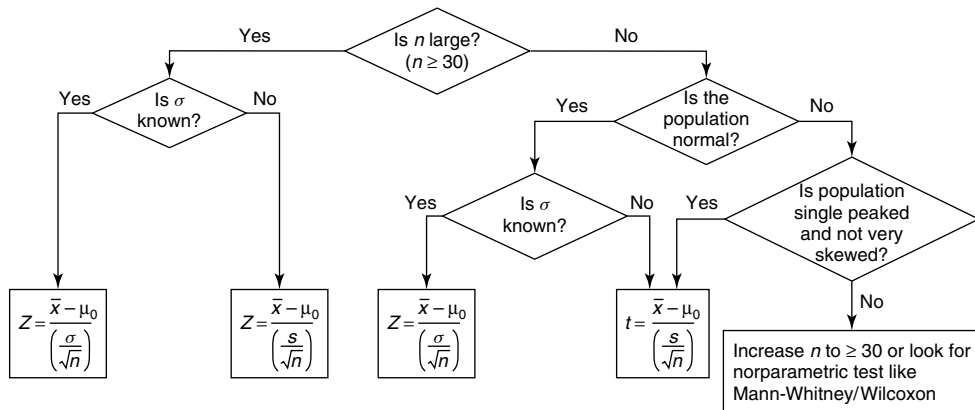

Figure 3 Selection of statistic for testing hypothesis about a population mean.

have developed an array of NONPARAMETRIC TEST (see also Conover, 1999).

We have provided tests for difference in means and proportions for large as well as for small samples above. With regard to small samples, an alternative to the suggested tests is known as *bootstrap statistics* (Mooney and Duval, 1993). Bootstrap statistics is a relatively new computer-intensive, general-purpose approach to statistical inference, falling within a broader class of resampling methods.

Bootstrapping involves taking a number of resamples of the observed dataset each of which is obtained by random sampling with replacement from the original dataset. Bootstrapping may also be employed for constructing hypothesis tests. It is often used as an alternative to inference based on parametric assumptions when assumptions are doubtful, or where parametric inference is not possible or requires complicated formulas for the calculation of standard errors. An alternative to Bootstrapping is known as *jackknife statistics* (Shao and Dongsheng, 1996).

Figure 3 provides a decisional diagram for selecting the appropriate statistical test for the mean.

INTRODUCTION

Latent class analysis and more generally finite mixture models have seen increased use in marketing since the early 1980s. The popularity of latent class and finite mixture models can, in large measure, be traced to the important role individual differences (i.e., heterogeneity) play in understanding marketing and consumer behavior phenomenon. At the most basic level, latent class and finite mixture models have allowed marketing researchers to account for individual heterogeneity when estimating model parameters. Our objectives in this article are to provide an overview of latent class and finite mixture models and to provide a brief discussion of the various model forms and application settings that have relied on latent class and finite mixture models to account for individual-level heterogeneity.

BASIC MODEL FORMS

Latent class and finite mixture models refer to a class of model forms that recognize that not all individuals (of a population) are strictly alike. The term “latent” is used since the heterogeneity cannot be directly observed and the terms “class” or “finite mixture” are used to because the population is assumed to consist of homogeneous subgroups (or discrete classes), often referred to as the *components of the mixture*. We begin with a discussion of the more general finite mixture model and then turn our attention to the latent class model. A comprehensive treatment of many of the latent class and finite mixture models discussed herein, as well as others, can be found in Wedel and Kamakura (2000). Readers interested in more details on mixture distributions can refer to Titterton, Smith and Makov (1985).

Finite mixture models. Letting $f_s(y|\theta_s)$ be the probability density for observation Y , when sampled from the s th subgroup and α_s the fraction of the population that belongs to subgroup s , where $\alpha_1 + \alpha_2 + \dots + \alpha_S = 1$, then Y has the

mixture density of the form

$$f(y|P) = \sum_{s=1}^S \alpha_s f_s(y|\theta_s) \quad (1)$$

In Equation 1 P denotes the collection of unknown parameters $(\alpha_s, \theta_s), s = 1, 2, \dots, S$. Put simply, the α 's reveal the size of each of the subgroups, whereas the θ_s parameters reveal the distinctive character of each subgroup. Each individual in the population is assumed to belong to one of the S subgroups, denoted by C_1, C_2, \dots, C_S , where subgroup membership for individual n is indicated by a $(S \times 1)$ vector z , with $z_s = 1$ if $y \in C_s$ and $z_s = 0$ otherwise; z is unobserved and is generally assumed to have a multinomial distribution, that is, $f(z|\alpha) = \prod_s \alpha_s^{z_s}$.

The conditional densities $f_s(y|P_s)$ can assume a variety of different multivariate distributional forms. For example, $f_s(y|P_s)$ can represent the multivariate normal or the multinomial distributions. When distributions are assumed to be discrete, for example, binomial, multinomial, or Poisson, finite mixture models are generally referred to as *latent class models*.

Parameters of the finite mixture model can be obtained via maximum likelihood (ML) estimation. For mixture distributions, the likelihood function assumes the following general form:

$$L(Y, P) = \prod_{i=1}^N \left(\sum_{s=1}^S \alpha_s f_s(y_i, \theta_s) \right) \quad (2)$$

By differentiating Equation 2 with respect to the elements of P , one can obtain the corresponding normal equations. It turns out that the ML estimates of α_s , the *mixing proportion* associated with subgroup s , is given by the sample mean of the posterior probability that y_i comes from that subgroup. Similarly, ML estimates of the θ_s parameters can be derived in the case where these parameters have explicit solutions by taking a weighted average of the ML equations, where the weights are the posterior probabilities.

ML estimates of the finite mixture model parameters have been obtained either by applying standard numerical optimization methods or the expectation maximization (EM)

2 latent class and finite mixture models

algorithm (Dempster, Laird and Rubin, 1977). In the first approach, numerical optimization techniques, for example, the Newton-Raphson, simplex, or Fisher's scoring, are applied to the finite mixture model normal equations directly. In the EM approach unknown parameters are seeded with initial values and then the algorithm cycles through an *Expectation* (*E*) step and a *Maximization* (*M*) step. In the *E*-step the "missing data" (i.e., the subgroup that each individual belongs to) are estimated using the initial set of parameter start values and these "estimates" are then used to compute the posterior probabilities of subgroup membership. In the *M*-step, these "estimated" posterior probabilities are then used to obtain revised values of α 's and θ 's. The process cycles back to the *E*-step and continues in a similar fashion until the change in likelihood function values from one cycle to the next is judged to be small.

In empirical work, the number of subgroups S is not known and has to be inferred. The overwhelming temptation is to use the standard likelihood ratio test statistic, which is formed by taking 2 times the difference in the log-likelihood values for the s versus $s + 1$ subgroup solutions. Typically, the likelihood ratio test statistic computed in this way has a chi-square distribution; however, in the case of mixtures, the test statistic is not asymptotically chi-square since the s subgroup model is at the boundary of the parameter space for the $s + 1$ subgroup model. Because of this, a number of information statistics have seen use, all of which have the general form $-2 \ln(L) + Qd$, where Q is the number of parameters and d is a penalty taking on different forms for different statistics. The oldest of the information statistics is Akaike's AIC in which $d = 2$. Two other information statistics that have been used are the Schwarz's BIC, which sets $d = \ln(N)$, and Bozdogan's CAIC, which sets $d = \ln(N) + 1$. The number of subgroups to retain is given by the model that produces the minimum value of the chosen information statistic. BIC and CAIC offer the advantage of being dimension consistent; that is, the probability of the statistic pointing to the correct number of subgroups converges to one as the sample size increases.

There are also a number of other bootstrap-type approaches. For example, Dillon and

Mulani (1984) use a parametric bootstrap testing approach in which $T-1$ random Monte Carlo samples of size N are drawn from a population having s subgroups with conditional density $f_s(y|P_s)$. A finite mixture model is then fit with s and $s + 1$ subgroups to each of the generated samples and the likelihood ratio statistic is computed. If the value of the likelihood ratio statistic obtained from the observed data exceeds $T(1 - p)$ of the likelihood values obtained in the Monte Carlo samples, where p is the desired significance level, then the null hypothesis that the models with s and $s + 1$ subgroups fit equally well cannot be accepted. Since this test and the three information statistics just described are based on the likelihood ratio statistic, all of these approaches should be viewed as heuristics.

Another important element in both latent class and finite mixture models are the *posterior probabilities*. Posterior probabilities give the probability that an individual belongs to each of the S subgroups and play an important role in the estimation process and in profiling the subgroups. The posterior probabilities are computed using Bayes rule and the estimated finite mixture parameters $(\hat{\alpha}_s, \hat{\theta}_s)$:

$$\hat{\pi}_s = f(z_s|y; \hat{P}) = \frac{\hat{\alpha}_s f_s(y|\hat{\theta}_s)}{\sum_{s'} \hat{\alpha}_{s'} f_{s'}(y|\hat{\theta}_{s'})} \quad (3)$$

In empirical work, the posterior probabilities are often of particular interest as they are used as "new variables" in subsequent analyses to profile the segments and to explain subgroup membership as well as to assess the "quality" of the solution by forming an entropy-type measure.

Concomitant finite mixture models.

Concomitant finite mixture models come about when one makes a distinction between variables that are chosen to form the basis on which the subgroups are identified (i.e., take on meaning) and another set of variables that are used to describe the subgroups and subgroup membership. We continue to denote the basis or core set of variables by y and now denote the concomitant or profile variables by x . There are two general types of concomitant finite mixture models. The first class of models include the core and descriptor variables simultaneously

within the finite mixture model and therefore attempt to identify the subgroups and, at the same time, discriminate across the subgroups, akin to discriminant analysis. Under this model form we can rewrite Equation 1 as

$$f(y, x|P) = \sum_{s=1}^S \alpha_s f_s(y|\theta_s) f_s(x|\phi_s) \quad (4)$$

Here, conditional independence of the y and x variables given s is explicitly assumed, and, consequently, there is no need to denote these two variable types, other than for clarity of exposition.

In contrast, the second general model form treats the two set of variables very differently and uses the set of concomitant variables to simultaneously describe the subgroups. Although many variations of this approach have been proposed, one popular variant is to parameterize the prior probabilities as functions of the concomitant variables using the logit function:

$$\pi_{s|x} = \frac{\exp(\gamma_{0s} + x' \gamma_s)}{\sum_{s'} \exp(\gamma_{0s'} + x' \gamma_{s'})} \quad (5)$$

In Equation 5, γ_{0s} and γ_s are set to zero for identification. The specification of this finite mixture concomitant variable model now assumes the following form:

$$f(y|x; P) = \sum_s \pi_{s|x} f_s(y|\theta_s) \quad (6)$$

where $P = (\gamma_{0s}, \gamma_s, \theta_s)$. A comprehensive treatment of latent concomitant variable model forms can be found in Wedel (2002).

Latent class models. Letting y_i denote the response vector for the i th individual, where y_{ij} are polytomous responses, $r = 1, \dots, R_j$, for $j = 1, \dots, J$ random categorical variables, and $c \in C, s = 1, \dots, S$, denote the S latent classes, a general latent class model is defined by

$$f(Y_i, c_s) = \prod_{j=1}^J \prod_{r=1}^{R_j} [\theta_{jrs}]^{\delta_{ij}} \quad (7)$$

and

$$f(Y_i, P) = \sum_{s=1}^S \alpha_s f(Y_i, c_s) \quad (8)$$

where δ_{ij} is the Kronecker delta, which assumes a value of one if $y_{ij} = r$ and zero otherwise. Note that in addition to the usual constraint that, $\sum \alpha_s = 1$, it must also hold that $\sum_{j=1}^{R_j} \theta_{jrs} = 1$ for all j, s . The similarity of the latent class model defined by Equations 7 and 8 along with the appropriate constraints, and the finite mixture model should be obvious. However, there is one important difference, namely, the property that within a latent class the categorical variables are assumed to be statistically independent. This property, which is referred to as the *axiom of local independence*, means that within a latent class the joint densities can be expressed as a product of independent marginal densities. Though the property of local independence is used in other finite mixture models, it is not necessarily invoked in all varieties of finite mixture models. Both gradient methods and the EM algorithm have seen use in estimating the parameters (α_s 's and θ_{jrs} 's) of the latent class model, although, since the ML equations for the basic latent class model have closed-form solutions, the EM algorithm is particularly well suited for this class of models.

The flexibility of the basic latent class of model can be greatly enhanced by adopting a logistic reparameterization of the basic latent class parameters (α_s, θ_s) in terms of real-value auxiliary parameters (ω_s, z_{jrs}), respectively, where these auxiliary parameters are themselves expressed as functions of a set of covariates. One set of covariates is presumed to influence the latent class sizes and the other set is presumed to influence the latent class conditional probabilities. Formann (1992) refers to this model form as the *linear logistic latent class model*.

MODEL VARIANTS: APPLICATIONS AND PROBLEM SETTINGS

In this section, we provide a brief discussion of a number of latent class and finite mixtures model variants that have been proposed to address a wide variety of applications and problem settings.

Scaling models. Latent class scaling models have long history, dating back to the 1970s (cf. Goodman, 1975). These models impose a specific presumed scale structure on a set of

4 latent class and finite mixture models

dichotomous or polytomous responses. These model forms, which are made possible because of the ability to impose constraints on the latent class parameters, are of two general types. *Purely deterministic scaling models* assume the absence of measurement error. Perhaps the best example is Guttman scaling wherein items are presumed to form a hierarchy of difficulty of agreeing with each of the k items and latent classes are introduced, which are isomorphic with each scale type, by imposing restrictions on the θ_{jrs} parameters. In contrast, *probabilistic scaling models* explicitly recognize and incorporate response error into the model. Goodman (1975) develops a number of Guttman-like models that can accommodate response errors by either incorporating an “intrinsically unscalable class” or a constant error rate parameter that governs the expected frequency of response error within or across latent classes; in addition, there have been several latent class Rasch and IRT models proposed as well.

Agreement models. Latent agreement models attempt to investigate the extent to which two or more observers agree in their assessment (or rating) of some phenomena. Clogg (1981) has applied latent class models in this context and argued that latent class agreement models have three salutary benefits related to their ability to (i) take into account chance agreement, (ii) afford coefficients that have clear interpretation, and (iii) identify sources of (dis)agreement.

Multidimensional scaling models. Latent class multidimensional scaling (LCMDS) has extended the applicability of conventional multidimensional scaling (MDS) models by accommodating samples of respondents that would otherwise be too large and messy for standard MDS approaches – even today conventional MDS models are geared to either individual-level data or small sample sizes. (Conventional MDS procedures are discussed in MULTIDIMENSIONAL SCALING OF PREFERENCE DATA.) Put simply, LCMDS perform multidimensional scaling while simultaneously clustering respondents – in marketing vernacular, LCMDS simultaneously estimates market segments as well as perceptual or preference structures of consumers (who belong to each

of the latent segments). DeSarbo, Manrai and Manrai (1994) provide a comprehensive treatment of a variety of LCMDS models, including a generalized EM framework for the estimation of such models.

Regression models. Latent class regression models, or what are also referred to as *latent regression mixture models*, have been developed to explain the relationship between a set of independent, explanatory variables and a dependent variable when it is suspected that a single set of regression coefficients may be misleading because of respondent heterogeneity. (Multiple regression analysis is discussed in MULTIPLE REGRESSION) This class of models has its origins in the early work on “two-regime” switching regression models. A variety of latent class regression models have been developed to accommodate different distributional forms of the dependent variable. In the literature, we find latent class regression models for normal data (DeSarbo and Cron, 1988), for binary/multinomial data (Kamakura and Russell, 1989), for paired comparison data (Dillon, Kumar and de Borrero, 1993), and for count data (Wedel *et al.*, 1993). Mixtures of normals have seen extensive use in understanding preference and conjoint data, while mixtures of multinomials have been extensively used in the analysis of choice behavior. (Further details on conjoint analysis and logit models can be found in CONJOINT ANALYSIS and LOGIT MODEL, respectively.) A comprehensive treatment of the variety of latent class regression models that have been developed can be found in Wedel and DeSarbo (1994).

Structural equation models. Latent class structural equation models (SEMs) represent a fairly recent development (cf. Jedidi, Jagpal and DeSarbo 1997). (STRUCTURAL EQUATION MODELING in this volume of the encyclopedia discusses conventional SEMs.) Latent class SEMs allow the researcher to assess the measurement properties of a hypothesized theoretical model, that is, construct convergent and discriminant validity, disattenuate structural parameters between the exogenous “explanatory” constructs and the endogenous “dependent” constructs, while simultaneously

accounting for respondent heterogeneity. This class of models is analogous to fitting a multigroup structural equation model in the case where the groups are not directly known a priori. Latent class SEMs subsume a number of special cases. For example, if there are no endogenous constructs in the model, the model reduces to a finite mixture confirmatory factor model; if one assumes no measurement error, the model reduces to a mixture of simultaneous regressions or multivariate regressions.

Transition models. Latent class transition models represent a type of autoregressive modeling of longitudinal data. These model forms, which include hidden Markov models, consider several variables measured at each of several time points with a view toward explaining changes in the state variable. The state variable at one time point influences the state variable at the next time point in an autoregressive fashion. In these models two or more latent classes are introduced to distinguish between the state variable over time and, in so doing, assess true change from measurement error. Poulsen (1990) was the first to introduce the basic latent Markov model form.

Growth mixture models. Latent class growth analysis (LCGA) and growth mixture models (GMMs) are extension of conventional longitudinal growth analysis, which estimates mean growth curves that differ in intercepts and/or slopes. This analysis focuses on relating the repeated measurements of a dependent variable to a time-related variable (time scores), a time-varying covariate, and a time-invariant covariate, where the functional form of the relationship is parameterized in terms of random intercepts and slopes, which vary across individuals. In general, growth models can consider either continuous or categorical outcomes (dependent variables). LCGA and GMM extend these model forms by introducing latent classes that can either reflect homogeneous growth curves (i.e., members of a given latent class exhibit the same development) or capture the unique effects of a set of covariates on the within-class growth factors. Muthén (2004) provides a comprehensive summary of these model forms.

models for categorical dependent variables

Gary J. Russell

INTRODUCTION

Researchers in marketing collect vast amounts of information on consumer behavior. Some of this information is continuous (such as total dollar expenditure for detergents in a given year) or takes the form of counts (such as the number of detergent bottles purchased in the last two months). However, much consumer purchase information is only available in the form of categorical information. For the purpose of this article, we define a *categorical dependent variable* as a nominally scaled variable that either classifies a consumer into a group or records consumer response to the marketing environment. For example, using a scanner panel dataset, a researcher might construct a categorical variable that reports the brand name and package size of a detergent purchase on a shopping trip. A model for a categorical dependent variable, then, is a predictive model that allows the researcher to make inferences about a categorical response, using additional information about consumers and the marketing environment.

We begin with a general discussion of the problems encountered in developing models for categorical variables. Although regression-based procedures are inappropriate in these settings, we argue that statistical tools known as *generalized linear models* (GLMs) provide a convenient approach for model construction. We then turn to issues of model specification and interpretation. To assist in this task, we briefly outline random utility theory (RUT) and show its relationship to GLMs. We conclude with a brief discussion of complex models addressing issues such as heterogeneity in response parameters and correlations among categorical variables in a repeated measures context.

CONTINUOUS VERSUS DISCRETE VARIABLES

At the outset, it is useful to ask why researchers require distinct methodologies for dealing with categorical variables. Suppose, for example, the dependent variable y takes on two values, depending upon whether a consumer buys

Brand A ($Y = 1$) or Brand B ($Y = 2$). By assembling the responses for all consumers into a vector y , the researcher might analyze all observations in the dataset using regression software and obtain the coefficients β of the linear model $y = X\beta$. Here, X is a matrix containing information on consumer demographics and marketing mix variables (such as price and promotion). Some of the X variables are continuous, but others could be categorical or ordinal.

The problem with the regression approach is not the variety of different types of X variables. Rather, the problem is the forecasts of the regression model. Because regression assumes that the dependent variable is continuous, forecasts of the dependent variable y may, in principle, be any number, positive or negative. For example, suppose that the forecast of the model for a particular set of X variables is 1.2. Does this mean that the consumer would buy Brand A? Does it mean that the consumer would buy some of Brand A and some of Brand B? Suppose, instead, that the forecast were 3.5. Does this mean that the consumer would buy Brand B? How should -1.7 be interpreted?

The problem shown here is one of logical consistency. Because the forecasts of the regression model cannot be constrained to take on only the values of the categorical dependent variable, the face validity of the regression approach is questionable. From a statistical perspective, hypothesis tests of the regression coefficients (such as t -tests) are also invalid because these tests are constructed on the assumption that the dependent variable is drawn from a normal distribution. Clearly, the normality assumption makes no sense for categorical variables. Taken together, lack of logical consistency and lack of statistical validity strongly argue that the categorical dependent variables should be modeled using specialized methods.

GENERALIZED LINEAR MODELS

The key to modeling categorical dependent variables is to realize that, by definition, categorical dependent variables are discrete. Formally, if Y is a categorical dependent variable, then Y takes on one of R values for some known value R . We assume that, this variable is measured

2 models for categorical dependent variables

Table 1 Commonly-used GLM models in marketing research.

| <i>Name of Model</i> | <i>Type of Response Variable</i> | <i>Assumed Distribution of Response Variable</i> | <i>Mean of Response Variable $E(Y)$</i> | <i>Link Function $g[E(Y)]$</i> |
|----------------------|----------------------------------|--|--|--|
| Linear regression | Continuous | Normal | μ_h | $\mu_h \mathbf{x}(h)^T \beta$ |
| Poisson regression | Count | Poisson | λ_h | $\log(\lambda_h) \mathbf{x} = (h)^T \beta$ |
| Binary logit | Categorical ($R = 2$) | Binomial | $\pi(1)_h, \pi(2)_h$ | $\log[\pi(1)_h / (1 - \pi(1)_h)] = [\mathbf{x}(1, h) - \mathbf{x}(2, h)]^T \beta$ |
| Binary probit | Categorical ($R = 2$) | Binomial | $\pi(1)_h, \pi(2)_h$ | $F^{-1}(\pi(1)_h) = [\mathbf{x}(1, h) - \mathbf{x}(2, h)]^T \beta$, where $F^{-1}(\cdot)$ is the inverse of a $N(0,1)$ cdf |
| RUT logit | Categorical ($R > 2$) | Multinomial | $\pi(1)_h, \dots, \pi(R)_h$ | $\log[\pi(k)_h / \pi(R)_h] = [\mathbf{x}(k, h) - \mathbf{x}(R, h)]^T \beta$ for $k = 1, 2, \dots, R - 1$ |
| Common logit | Categorical ($R > 2$) | Multinomial | $\pi(1)_h, \dots, \pi(R)_h$ | $\log[\pi(k)_h / \pi(R)_h] = \mathbf{x}(h)^T \beta(k, R) \beta(k, R) = [\gamma(k) - \gamma(R)]$ for $k = 1, 2, \dots, R - 1$ |

on a nominal scale. That is, the numbers used to represent the R outcomes of Y convey no ordinal information, and certainly cannot be regarded as continuous measures. For example, in an analysis of the detergent market, the researcher might choose $R = 3$, and then assign the following values: $Y = 1$ (Tide), $Y = 2$ (Wisk), and $Y = 3$ (Cheer). In this article, we do not discuss how a categorical scale should be constructed. However, in general, the researcher must ensure that the classification covers all possible outcomes and that it uniquely assigns each outcome to one value of the Y variable.

The modeling strategy for a categorical dependent variable discards the idea that Y can be predicted directly. Instead, the researcher defines the probabilities $\pi(1), \pi(2), \dots, \pi(R)$, where $\pi(j)$ is interpreted as the probability that Y takes on the value j . Because the $\pi(j)$ are probabilities, they must obey two logical constraints: all the $\pi(j)$ fall between the values 0 and 1, and the sum $\pi(1) + \dots + \pi(R) = 1$. For example, when data analysis is conducted at the consumer level, we interpret $\pi(j)$ as the probability that

the individual selects (or obtains) outcome j . The goal of the analysis, then, is to forecast the full set of probabilities that cover all the outcomes of Y . This implies that the researcher cannot predict with certainty which of the R outcomes will be actually observed. Putting this in statistical language, the strategy of the researcher is to predict the discrete probability distribution of Y , and not the actual realization of Y itself.

GLM modeling approach. One attractive way of implementing this strategy is to generalize regression analysis to deal with response variables that are not continuous. This is the approach taken by the GLM methodology (McCullagh and Nelder, 1989). When using the GLM approach, the researcher retains the idea that a linear predictor of the form $X\beta$ should be used to forecast the mean of the response variable. However, the distribution of the response variable need not be normal, and the link between the linear predictor and the mean response can be quite complex.

A summary of GLM models often found in marketing research is displayed in Table 1.

Briefly, the GLM methodology is built on the following key assumptions:

1. The response variable is some member of the exponential family of distributions. These include the normal, Poisson, binomial, and multinomial distributions, among others. As shown in Table 1, the binomial and multinomial distributions are appropriate for modeling categorical response variables.
2. The dataset contains $h = 1, 2, \dots, N$ observations. We assume that the response variables are statistically independent across these N observations. This implies, in particular, that any dependence across observations must be built into the model by linking the means of the response variables across observations. Correlation structures across errors (such as serial correlations in a time series context) are not allowed.
3. The relationship between the linear predictor is given by a link function. Formally, a link function is some monotonic continuous function of the mean of the response variable of the form $g[E(Y)]$, where $E(Y)$ is the mean value of Y . In Table 1, we list the most common link functions used in practice. For a categorical response variable, researchers typically assume that the natural log of the ratio of outcome probabilities is equal to the linear function of the independent variables. Notice that, each link function allows the linear predictor to take on any value, positive or negative. For this reason, the estimated vector of parameters β is left unrestricted, a fact that simplifies model calibration. Nevertheless, the implied mean for the response variable will always obey the necessary logical constraints. For example, the binomial and multinomial models for categorical response variables generate a set of forecasted probabilities that lie between 0 and 1, and sum to 1 across all outcomes. Thus, by using an appropriate GLM, the researcher will obtain logically consistent forecasts.

SPSS. The basic strategy is to write out the likelihood function of the GLM specification and then to maximize the likelihood with respect to the parameters β . As explained in McCullagh and Nelder (1989), a GLM model likelihood has a special structure that allows an iteratively weighted least squares routine to be used to generate parameter estimates. The important point for applied researchers is that, GLM models are numerically stable and converge quite rapidly. Standard errors of parameters are obtained via a transformation of the matrix of second derivatives of the log-likelihood function.

There is a strong temptation in GLM modeling to always interpret the β coefficients in the same manner as regression coefficients – even when the response variable is categorical. This is incorrect for two reasons. First, as noted above, the linear predictor $X\beta$ in a model with a categorical response variable does not yield a forecast of Y . Instead, it yields a highly nonlinear function of the mean of Y . Second, when analyzing categorical data, the researcher is actually fitting a discrete probability distribution to the R possible values of Y . Extreme care must be taken in both specifying the GLM model and in interpreting the results.

The well-known R^2 statistic for regression models cannot be used to assess the fit of a GLM model with a categorical dependent variable. Again, the problem is that R^2 is designed for continuous variables. An attractive alternative is the ρ^2 statistic (Louviere, Hensher, and Swait, 2000). The logic of the statistic relies on the observation that the likelihood of a categorical response GLM model is the product of probabilities across all observations – and so cannot exceed the value one. Accordingly, the log-likelihood (LogL) of any given model cannot be larger than zero. The procedure is to fit two models: one, a simple model with very few parameters, and the other, a more complex model with all the variables of interest. Then, using the LogL of the simple model (LogL(s)) and the LogL of the complex model (LogL(c)), we define

$$\rho^2 = \frac{[\text{LogL}(s) - \text{LogL}(c)]}{\text{LogL}(s)} = 1 - \frac{\text{LogL}(c)}{\text{LogL}(s)} \quad (1)$$

GLM calibration and fit. Calibration of a GLM model is quite easy, because of readily available statistical software packages such as SAS and

4 models for categorical dependent variables

This statistic lies between 0 and 1, with higher values indicating better fit. Extensive experience with real-world datasets indicates that models with excellent fit will have a ρ^2 value between 0.2 and 0.4 (Louviere, Hensher, and Swait, 2000). The choice of the simple model is somewhat controversial. However, most researchers choose a model that forces the discrete probability distribution of Y to be identical for all observations in the dataset.

MODELING MULTINOMIAL RESPONSES

From the standpoint of applied research in marketing, the most difficult aspect in modeling categorical response data is developing an interesting way of predicting the probabilities of response $\pi(1)_h, \dots, \pi(R)_h$. Although, the link functions shown in Table 1 are commonly used in marketing research, they are not the only choices available. We first discuss the properties of the models in Table 1, and then turn to a variety of alternatives.

Let h denote an observation and k denote one of the R categorical values of the response variable Y . We assume that for each h and k , the researcher has access to Q independent variables in the form of the vector

$$\mathbf{x}(k, h) = [x(k, h, 1), x(k, h, 2), \dots, x(k, h, Q)]^T \quad (2)$$

At the outset, it is important to note that these variables can be either continuous variables or (dummy-coded) categorical variables. For example, if the goal of the model is to predict brand choice, h might denote a household and k a particular brand of detergent selected on a shopping trip (see PURCHASE, SCANNER, AND MEDIA PANELS). Then, we might define one variable of $\mathbf{x}(k, h)$ to be the price of brand k observed by household h during the purchase occasion. We could also define another component of $\mathbf{x}(k, h)$ to be a binary (0,1) indicator variable for which the value 1 denotes the presence of a promotion for brand k during the shopping trip. It is customary to include an intercept variable in each $\mathbf{x}(k, h)$ to represent the average level of $\pi(k)_h$ across all observations. These are $R - 1$ binary (0-1) indicator variables of the form $x(k, h, q) = 1$ only if $k = q$. For reasons

that will become clear shortly, $\mathbf{x}(k, h, R)$, the intercept for the R th outcome provides redundant information and so should not be included in the model.

The models for categorical response shown in Table 1 are known as *logit models* (see LOGIT MODEL). For the $R > 2$ case, researchers generally use the term *multinomial logit*. Consider the link function

$$\log \left[\frac{\pi(k)_h}{\pi(R)_h} \right] = [\mathbf{x}(k, h) - \mathbf{x}(R, h)]^T \beta \quad (3)$$

for $k = 1, 2, \dots, R - 1$. Using the fact that the probabilities $\pi(1)_h, \dots, \pi(R)_h$ must sum to 1, we obtain the general expression

$$\pi(k)_h = \frac{\exp [\mathbf{x}(k, h)^T \beta]}{\{\exp [\mathbf{x}(1, h)^T \beta] + \dots + \exp [\mathbf{x}(R, h)^T \beta]\}} \quad (4)$$

where $\exp[\cdot]$ denotes the exponential function and the summation in the denominator runs over the R possible outcomes of the response variable. Equation 4 is the familiar “us versus (us + them)” formulation for probabilities and market shares often used in the marketing research literature.

Logit model identification. It must be emphasized that the link between independent variables and the probability of response is highly nonlinear. Accordingly, the researcher must take great care in choosing independent variables to include in the $\mathbf{x}(k, h)$ vectors. To understand the key issues, notice that the logit link function in Equation 3 is defined in terms of the differences between two vectors of variables $[\mathbf{x}(k, h) - \mathbf{x}(R, h)]^T \beta$. Because these link functions define the response outcome probability distribution, we must conclude that only the differences between the independent variables of the various outcomes impact model fit.

This can lead to problems in some applications. For example, suppose that h denotes household and that the researcher wishes to examine the impact of household income on the response variable. Denote income as $\mathbf{x}(k, h, q)$. (That is, income is the q th variable in the

vector $\mathbf{x}(k, h)$.) Because income depends upon household h , but not upon outcome k , it must be the case that $x(k, h, q) = x(k^*, h, q)$ for any alternative k^* different from k . Put another way, $[x(k, h, q) - x(k^*, h, q)] = 0$ because all these variables have the same value, namely, the income of the household. In statistical jargon, the coefficient on household income is said to be *unidentified* under these circumstances. If the researcher ignores this logical constraint and attempts to estimate the multinomial logit using GLM software, the algorithm will fail to converge because there exists no unique value of the response coefficient vector β that maximizes the likelihood function. Using a slightly more complex argument, it can also be shown that the R th outcome intercept is unidentified in the presence of intercepts for outcomes $1, 2, \dots, R-1$. An excellent discussion of identification issues in the context of a categorical response variable model may be found in chapter 2 of Train (2003). In general, independent variables are only useful if they impact the relative sizes of the outcome response probabilities.

Model identification issues can be addressed by using theory (from psychology or economics) to suggest how variables should enter the model. For example, Kalyanam and Putler (1997) use microeconomic theory to argue that household income should impact choice in the form of an *interaction* between price and income. (In this context, interaction means that the price of a particular outcome should be multiplied by household income.) Accordingly, these authors estimate a multinomial logit model including two price variables: brand price, and the interaction of brand price, and household income. They show empirically that higher income households are less price sensitive than lower income households. Clearly, some variables cannot be used directly in the $\mathbf{x}(k, h)$ vector, but can be introduced in a special way (using interactions) to modify the β coefficients of other variables (such as price).

RUT logit model. The major justification for Equation 4 is RUT. Briefly, the RUT paradigm assumes that consumer h assigns a utility $U(k, h)$ to each of the possible alternatives according to

the expression

$$U(k, h) = \mathbf{x}(k, h)^T \beta + \varepsilon(k, h) \quad (5)$$

where $\varepsilon(k, h)$ is a stochastic error term reflecting unobservable factors that influence choice. On each choice occasion, the consumer is assumed to select the product k that yields maximum utility. Because the error is unobserved, RUT requires the analyst to use the stochastic properties of the $\varepsilon(k, h)$ variables to derive the probability that alternative k will be chosen. If the $\varepsilon(k, h)$ are independent draws from a Gumbel (extreme value) distribution, then the choice probabilities $\pi(k)_h$ can be shown to be equal to the multinomial logit model of Equation 4.

Detailed discussions of RUT and the logit model can be found in Ben-Akiva and Lerman (1985), Louviere, Hensher, and Swait (2000), and Train (2003). The classical marketing application of the multinomial logit to scanner panel data is Guadagni and Little (1981). This article also provides excellent practical advice on the development of $\mathbf{x}(k, h)$ variables that capture consumer brand preference, choice process dynamics, and marketing mix effects.

Common logit model. Not all marketing research applications require a model that conforms to RUT. For example, consider the multinomial logit link function

$$\begin{aligned} \log[\pi(k)_h / \pi(R)_h] &= \mathbf{x}(h)^T [\gamma(k) - \gamma(R)] \\ &= \mathbf{x}(h)^T \beta(k, R) \end{aligned} \quad (6)$$

for $k = 1, 2, \dots, R-1$. Notice that, the vector of independent variables $\mathbf{x}(h)$ depends only on the observation h , not upon the alternative chosen. This implies the relationship

$$\pi(k)_h = \frac{\exp[\mathbf{x}(h)^T \beta(k, R)]}{\left\{ \exp[\mathbf{x}(h)^T \beta(k, R)] + \dots + \exp[\mathbf{x}(h)^T \beta(R, R)] \right\}} \quad (7)$$

where $\exp[\mathbf{x}(h)^T \beta(R, R)] = 1$ because the logic of Equation 6 requires $\beta(R, R) = \mathbf{0}$. An alternative (and logically equivalent) expression for the

probabilities is

$$\pi(k)_h = \frac{\exp[\mathbf{x}(h)^T \gamma(k)]}{\left\{ \exp[\mathbf{x}(h)^T \gamma(l)] + \dots + \exp[\mathbf{x}(h)^T \gamma(R)] \right\}} \quad (8)$$

where we assume (without loss of generality) that $\gamma(1) + \dots + \gamma(R) = 0$. Using Equation 8, it is easy to show that the link function of this model can be also written as

$$\log \left[\frac{\pi(k)_h}{\phi_h} \right] = \mathbf{x}(h)^T \gamma(k) \quad (9)$$

where ϕ_h is the geometric mean of the $\pi(k)_h$ probabilities. Again, we require that the sum of $\gamma(k)$ coefficients equals zero. Although, Equations 6-9 appear very different, they all describe the same model.

In the statistics literature, the relationship in Equation 8 is usually defined as a multinomial logit model. For clarity, we will refer to Equation 4 as the *RUT logit* model and Equation 8 as the *common logit* model. It should not be surprising that the specification issues of the common logit are very different from those of the RUT logit. The key property of the common logit is that the independent variables $\mathbf{x}(h)$ vary by observation h , but not by the level k of the outcome variable Y . In addition, the parameters of the common logit model (denoted $\gamma(k)$) vary by alternative. Recall, that the RUT logit specification has one common set of parameters (β) for the model, but a set of independent variables $\mathbf{x}(k, h)$ that vary by alternative. In a certain sense, the RUT logit and the common logit are mirror images of one another.

The common logit is often the only type of logit model that is supported by standard statistical software. The form of the model is motivated by the observation that

$$\begin{aligned} \log \left[\frac{\pi(k)_h}{\phi_h} \right] &= \log[\pi(k)_h] - \log[\phi_h] \\ &= \log[\pi(k)_h] - E_k[\log[\pi(k)_h]] \end{aligned} \quad (10)$$

where $E_k[\log[\pi(k)_h]]$ is the mean (over k outcomes) of the $\log[\pi(k)_h]$ values. (This follows

because ϕ_h is the geometric mean of the choice probabilities.) Accordingly, the Equation 9 link function requires that the linear predictor $\mathbf{x}(h)^T \gamma(k)$ be equal to the deviation of the log-probability of outcome k around the mean of the log-probabilities for all R outcomes.

This notion of modeling deviation scores using a linear model is very similar to the logic used by statisticians in developing ANOVA (analysis of variance) decompositions for factorial experiments (see ANALYSIS OF VARIANCE AND COVARIANCE). The fact that all the $\gamma(k)$ parameters sum to zero is fully consistent with standard ANOVA parameter-coding schemes. For this reason, if all the explanatory variables in $\mathbf{x}(h)$ are categorical, the researcher can directly use ANOVA coding to analyze a categorical outcome variable within the common logit framework. Moreover, it can be shown that the resulting model is actually a special case of a log-linear model. Log-linear models are Poisson regression models that allow the analysis of multiway contingency tables. Thus, there is an intimate connection between the common logit and contingency table analysis (see CROSS-TABULATION).

Interpretation of common logit parameters can be very difficult. For most applications, the researcher estimates the $\beta(k, R)$ coefficients (using Equation 7), and not the $\gamma(k)$ parameters (using Equation 8). For example, consider a choice model developed by Jank and Kannan (2005) using a generalization of the common logit model. Each consumer in the study was offered three alternatives: (i) buying a printed copy of a research article, (ii) buying a PDF version of the same article, or (iii) not buying the article in any format. We display the $\beta(k, R)$ coefficients reported by Jank and Kannan (2005) on the left-hand side of Table 2. On the right-hand side of Table 2, we display the corresponding $\gamma(k)$ coefficients, computed from the $\beta(k, R)$ estimates by using Equation 6 and the fact that the $\gamma(k)$ sum to zero across alternatives. Note that, each row of the $\gamma(k)$ section of Table 2 adds to zero, as required.

The prices of the print copy and the PDF electronic file are the key variables. Two versions of the PDF price are used: PDF price as a percentage of the print price, and PDF price in absolute units. Consistent with Equation 7,

Table 2 Common logit parameter estimates.

| | $\beta(k,R)$ Coefficients | | | $\gamma(k)$ Coefficients | | |
|------------------------|---------------------------|--------|------|--------------------------|--------|--------|
| | Print | PDF | None | Print | PDF | None |
| Intercept | 0.315 | 1.835 | 0 | -0.402 | 1.118 | -0.717 |
| Print price | -0.015 | 0.013 | 0 | -0.014 | 0.014 | 0.001 |
| PDF price (percentage) | 0.009 | -0.065 | 0 | 0.027 | -0.046 | 0.019 |
| PDF price (actual) | 0.097 | 0.038 | 0 | 0.052 | -0.007 | -0.045 |

The $\beta(k,R)$ coefficients are reported by Jank and Kannan (2005). The $\gamma(k)$ coefficients are inferred using the $\beta(k,R)$ values and the link function in Equation 6.

all variables enter into the expressions for all alternatives, and the column corresponding to the last alternative (nonpurchase, denoted by None) is set to zero. At a minimum, we would expect that the signs of the two versions of PDF price in the PDF column should both be negative (because higher PDF prices reduce the probability of buying the article in PDF format). This is not true in the PDF column of the $\beta(k,R)$ section of the table, but it is true in the PDF column of the $\gamma(k)$ section. This occurs because the $\beta(k,R)$ coefficients are measured relative to the R th level of the response variable (in this case, None), whereas the $\gamma(k)$ coefficients reflect deviations around the common geometric mean of all outcome probabilities.

LATENT VARIABLE MODELS

The RUT logit and common logit models are routinely used in marketing research applications. The models are easy to compute and often provide useful forecasts. Nevertheless, for some marketing applications, it is desirable to develop more complex models that take into account additional facts about the problem setting.

The conceptual tool that allows new models to be constructed is the notion of a latent variable. Simply put, a latent variable is a random variable whose outcomes cannot be directly observed. However, latent variables impact observed variables in a known way. In the context of the present discussion, a latent variable formulation allows the researcher to derive a new link between independent variables and the probability that the categorical outcome variable will take on certain values. This new link function, along

with the assumption of a multinomial distribution, allows the GLM framework to generate a new method of analyzing categorical response data.

Ordinal regression. The simplest model of this sort is ordinal regression. The model assumes that the R states of the categorical outcome variable can be ordered in a natural way owing to the manner in which the data were collected. For example, survey respondents might be given a five-point Likert scale and asked to rate a product in terms of preference. The researcher assumes that for each person h , there exists a latent preference variable

$$V(h) = \mathbf{x}(h)^T \beta + \varepsilon(h) \tag{11}$$

where $\varepsilon(h)$ is a random draw from some known distribution with mean zero. In other words, $V(h)$ is a random variable with mean $\mathbf{x}(h)^T \beta$.

The R points of the rating scale are assumed to correspond to $R - 1$ cut points ($\tau_1, \dots, \tau_{R-1}$) on the latent continuum of $V(h)$. If $V(h)$ falls below τ_1 , then the respondent picks the lowest point on the rating scale ($Y = 1$). If $V(h)$ falls between τ_1 and τ_2 , then the respondent picks the next higher point on the rating scale ($Y = 2$). This logic continues for all R outcomes of Y . By making distributional assumptions about the error $\varepsilon(h)$, it is possible to develop a formula for $\pi(k)_h$, the probability that respondent h (with background characteristics $\mathbf{x}(h)$) will have a $V(h)$ value that falls into the region of the latent continuum corresponding to $Y = k$. Using the GLM framework for multinomial distributions, the researcher is then able to obtain estimates of β and all the scale cut points $\tau_1, \dots, \tau_{R-1}$. This

procedure is known as *ordinal logistic* or *ordinal probit*, depending upon whether the distribution of $\varepsilon(h)$ is assumed to be logistic or normal, respectively. A detailed discussion of the model can be found in Bock (1975).

Random utility theory models. It should be now apparent that the latent preference Equation 11 is very similar to Equation 5, the expression for random utility introduced earlier in the context of the RUT logit model. In consumer choice applications, the general approach is to gather the utilities of all k alternatives into one vector $\mathbf{U}(h)$ and then write

$$\mathbf{U}(h) = X\beta + \mathbf{E}(h) \quad (12)$$

where each row of X contains equal $\mathbf{x}(k, h)^T$ and the k th element of the $\mathbf{E}(h)$ vector contains the error term $\varepsilon(k, h)$. As before, the RUT paradigm assumes that the consumer chooses alternative k if the utility $u(k, h)$ is the largest. Usually, we would write the model in Equation 12 in such a way that the mean of $\mathbf{E}(h)$ equals zero.

By assigning a specific multivariate distribution to the vector $\mathbf{E}(h)$, we can derive the probability that item k will have the maximum utility of all brands. This, of course, is $\pi(k)_h$, the probability that categorical outcome level k will be selected by consumer h . When the distribution of $\mathbf{E}(h)$ is a member of the generalized extreme value (GEV) family, the resulting probability expression is called a *GEV logit model* (Ben-Akiva and Lerman, 1985). Models of this sort are generalizations of the RUT logit discussed earlier. Alternatively, if $\mathbf{E}(h)$ has a multivariate normal distribution, then the probability expressions yield a *multinomial probit* model (Train, 2003). Both of these models can be viewed as different methods of linking the $X\beta$ linear predictor to the probability distribution of the categorical response variable. Thus, the GEV logit and the multinomial probit are also GLM models.

Computationally, GEV logit models are easier to estimate because the link functions have a known analytic form. In contrast, multinomial probit link functions are dependent upon an $R - 1$ dimensional integral. For this reason, researchers can simply append additional code to a multinomial response GLM algorithm to estimate a GEV logit model. In contrast, estimation

of multinomial probit parameters requires the use of simulation estimation technology to make the estimation of parameters practical. Train (2003) is an excellent source of information on simulation approaches to model calibration.

Both the GEV logit and the multinomial probit allow the researcher to alter the probability distribution of the outcome variable in a complex manner. Consider, for example, the nested logit model, a type of GEV logit that assumes a partitioning of the choice alternatives into subgroups. Let $\pi(s, j(s))_h$ denote the probability of selecting product $j(s)$ within the subgroups. The nested logit model decomposes this probability as

$$\pi(s, j(s))_h = \pi(s)_h \pi(j(s)|s)_h \quad (13)$$

where $\pi(s)_h$ is the probability of selecting subgroups, and $\pi(j(s)|s)_h$ is the probability of selecting product $j(s)$, given that subgroup s has been selected. In this model, $\pi(j(s)|s)_h$ takes the form of an RUT logit for brands within the submarket. The first term, $\pi(s)_h$, is also a logit model, but includes a specialized variable (called the *inclusive value*) that measures the relative attractiveness of each subgroup. Derivation of the nested logit model (and other GEV logit models) can be found in Ben-Akiva and Lerman (1985). Models with properties similar to the nested logit can also be constructed using the multinomial probit framework. See Train (2003) for details.

Parameter heterogeneity. Another important use of latent variables is the modeling of UNOBSERVED HETEROGENEITY in link function parameters. Researchers in marketing, generally, assume that consumer characteristics, (about which the researcher has limited knowledge) will induce variation in the β -portion of the GLM linear predictor. For example, suppose we rewrite the link function of Equation 3 as

$$\log \left[\frac{\pi(k)_h}{\pi(R)_h} \right] = [\mathbf{x}(k, h) - \mathbf{x}(R, h)]^T \beta(h) \quad (14)$$

where the parameter vector $\beta(h)$ is now allowed to depend on h . Equation 14 then implies an RUT logit model for each observation h , but

with parameters that vary across h . To calibrate a model of this sort, $\beta(h)$ is treated as latent variable drawn from some known distribution. *Latent class models* (Kamakura and Russell, 1989; Wedel and Kamakura, 1997) assume that the probability distribution of $\beta(h)$ is discrete (see LATENT CLASS AND FINITE MIXTURE MODELS). An E-M (expectation-maximization) algorithm can then be used to calibrate the model. *Random coefficient models* assume that the distribution of $\beta(h)$ is continuous. Most random coefficient models are now calibrated using a hierarchical Bayes technology (Rossi, Allenby, and McCulloch, 2005) (see RANDOM COEFFICIENTS MODELING). In either case, specialized algorithms are required for a GLM model with unobserved parameter heterogeneity.

MULTIVARIATE CATEGORICAL DATA

One of the most challenging forecasting problems in marketing research is the modeling of multivariate categorical data. To fix ideas, define $Y(h, j)$ as a categorical variable for respondent h . Instead of just one Y , we assume the researcher has access to M different categorical variables ($j = 1, 2, \dots, M$) arranged as a column vector

$$Y(h) = [Y(h, 1), Y(h, 2), \dots, Y(h, M)]^T \quad (15)$$

In the language of experimental design theory, the M variables $Y(h, j)$ are called *repeated measures* on respondent h . For example, in a survey analysis setting, index j could stand for different product names. In this context, the $Y(h, j)$ might be preference ratings for M different products on a Likert scale. Alternatively, in a panel data setting, index j could be defined as the time of the purchase occasion. Then, the $Y(h, j)$ would denote M different product choices (at M different times) by respondent h . The key question is how to adapt the univariate GLM framework discussed earlier to modeling the multivariate $Y(h)$ vector.

Conditional independence. Three different solutions have appeared in the marketing literature. By far, the most common approach is to assume that the repeated measures of respondent h are *conditionally independent*. The basic idea is to assume that the parameter vector of the link function for each $Y(h, j)$ is $\beta(h)$, a set of parameters

that do not depend on the particular categorical variable j being modeled. Moreover, given the $\beta(h)$ vector for respondent h , the M outcome variables in $Y(h)$ are assumed to be statistically independent. Conditional independence allows the researcher to treat repeated measures as independent univariate GLM models, subject to the restriction that all the link functions of respondent h have the same set of parameters. Correlations between the $Y(h, j)$ can be introduced into the model, but only by using the link functions to connect the $\pi(k)_h$ outcome probabilities of the various categorical variables. Guadagni and Little (1981) provide an interesting illustration of the conditional independence approach. They define the index j to be choice occasion (time) and allow the current choice probabilities to depend upon the past realizations of $Y(h, j)$.

Multivariate probit. The second approach involves generalizing the latent variable system introduced earlier in Equation 12. Suppose that we partition the $U(h)$ utility vector as

$$U(h) = [U(h, 1), U(h, 2), \dots, U(h, M)]^T \quad (16)$$

where $U(h, j)$ contains the set of utilities needed to predict the outcome of $Y(h, j)$. Consistent with RUT, we assume that the alternative with the highest value among the elements of $U(h, j)$ will become the alternative reported by $Y(h, j)$. Aside from this partitioning of the $U(h)$ vector, the basic RUT framework of Equation 12 is retained. If we assume that $E(h)$ is drawn from a multivariate normal distribution, then the researcher can derive the probability that item k will be the outcome for $Y(h, j)$. However, because the errors in $E(h)$ are correlated across the $Y(h, j)$ variables, the outcome probabilities of the $Y(h, j)$ categorical variables will be correlated as well. This approach is known in the marketing literature as the *multivariate probit* model. (It should not be confused with the multinomial probit model discussed earlier.) An application of the multivariate probit to market basket analysis is found in Manchanda, Ansari, and Gupta (1999).

Autologistic regression. The third approach is to view the $Y(h)$ vector as a random draw from a multivariate distribution for M categorical variables. For example, suppose that each of the

$Y(h,j)$ are binary (0–1) indicator variables, and define $\tau(j)_h$ as the *conditional probability* that $Y(h,j)$ equals 1, given the known outcomes of all other variables $Y(h,r)$ for all r different from j . Further, define the link function

$$\log \left[\frac{\tau(j)_h}{(1 - \tau(j)_h)} \right] = \mathbf{x}(h,j)^T \boldsymbol{\beta} + \sum_{i \neq j} \theta(i,j) Y(h,i) \quad (17)$$

where $\mathbf{x}(h,j)$ are explanatory variables and the $\theta(i,j)$ are symmetrical parameters ($\theta(i,j) = \theta(j,i)$) measuring the association among the $Y(h,j)$ outcomes. Equation 17 is called an autologistic regression *model* because the outcome of $Y(h,j)$ depends on all other variables in $\mathbf{Y}(h)$. It is possible to show that the M link functions corresponding to Equation 17 imply that the joint distribution of the $Y(h,j)$ variables is given by an M -dimensional *multivariate logistic* distribution. The amount of correlation between the $Y(h,j)$ is controlled by the $\theta(i,j)$ parameters. If all the $\theta(i,j)$ are equal to zero, then each of the $Y(h,j)$ variables is a statistically independent binary logit GLM. Russell and Petersen (2000) use the multivariate logistic model to analyze the impact of price within and across four paper goods categories. Generalizing this theory for multivariate R -level categorical variables remains a topic for future research.

SUMMARY

The analysis of categorical dependent variables requires special care in both model specification and parameter interpretation. Researchers must understand that models for categorical data are designed to forecast the discrete probability distribution of categorical outcomes, not the specific outcome itself. By far, the most prominent analysis tools used in marketing research are the RUT logit and the common logit. These models can be viewed as special types of GLMs. More complex models can be developed through the use of latent variables. In particular, latent variables permit the construction of models

that incorporate ordinal relationships among outcomes, differing patterns of similarity among alternatives, and heterogeneity in response parameters. Recent research has begun the development of multivariate models that allow for correlations among categorical dependent variables.

multidimensional scaling of preference data

Wayne S. DeSarbo and Crystal J. Scott

INTRODUCTION

Using the broad conceptualization by Carroll and Arabie (1980), we define multidimensional scaling (MDS) as a family of various geometric models for the multidimensional representation of the structure in data as well as the corresponding set of methods for fitting such spatial models. Carroll and Arabie (1980) present a taxonomy of the area of MDS based on the properties of the input measurement data (e.g., number of modes, number of ways, power of the mode, scale type, conditionality, completeness of the data, and replications) and properties of the underlying multidimensional measurement model (e.g., type of geometric model, number of sets of points in the derived space, number of derived spaces, and degrees of constraint on model parameters). Thus, their definition extends classical MDS, which typically deals only with spatial models for proximity data (e.g., similarities) to various other types of continuous and discrete representations, as well as to other data types. Our focus is upon two major types of models used for the analysis of two-way dominance data (i.e., preference, consideration to buy, or choice data) as is typically collected in marketing research: the vector MDS model and the unfolding MDS model. Readers interested in a more comprehensive discussion of this broad area of MDS are encouraged to read the very comprehensive book by Borg and Groenen (2005) for an in-depth treatment of these and other types of MDS approaches for the analysis of such data (e.g., correspondence analysis). For expository purposes, we assume that the data to be analyzed is a two-way data set of metric brand preferences where the rows of this data matrix (\mathbf{P}) reflect a sample of consumers and the columns of the matrix reflect brands in a designated product/service class. The general entry in this data matrix (P_{ij}) is therefore, the metric preference rating (see PRIMARY SCALES OF MEASUREMENT) given for brand j by consumer i . The objective of the MDS models to be described is to estimate a spatial configuration (a joint space) of both

row (consumers) and column (brands) objects such that their geometric interrelationships most parsimoniously recover the input preference data \mathbf{P} .

THE VECTOR MDS MODEL

Tucker (1960) and Slater (1960) were the first to independently formulate this scalar products based model for geometrically displaying the structure in such two-way data (Carroll, 1980). Related to factor analysis (see EXPLORATORY FACTOR ANALYSIS), the underlying model can be mathematically represented as

$$P_{ij} = \sum_{t=1}^T a_{it}b_{jt} + e_{ij} \quad (1)$$

where

$i = 1, \dots, I$ consumers;

$j = 1, \dots, J$ brands;

$t = 1, \dots, T$ dimensions;

a_{it} = the t th coordinate of the terminus of the preference vector for consumer i in the derived space;

b_{jt} = the t th coordinate of the location of brand j in the derived space;

e_{ij} = error.

We explain this geometric representation via Figure 1 that illustrates the workings of this particular model in Equation (1) for the simple case of two dimensions, four brands, and three consumers. The two dimensions are labeled as such in the figure and represent typical scatter plot axes. The brand coordinates (b_{jt}) are plotted here for each of the four brands (A, B, C, and D) and represent the positions of the brands in this derived space. Note, the consumer locations (a_{it}) are represented in this model (labeled Consumers 1, 2, and 3) as vectors emanating through the origin whose orientations point in the direction of increasing preference or utility for each consumer. Each of the three consumers' vectors point in different directions reflecting heterogeneity in their respective tastes and preferences. (Note that, we draw the tails of the vectors as dashed lines reflecting the areas of the space that are not preferred for each consumer).

Figure 1 The vector model.

The predicted cardinal preference values are given by the orthogonal projection of each of the brands onto each consumer's preference vector. Thus, Consumer 1 has the following order of predicted preference: B, C, A, D; Consumer 2: A, D, B, C; and Consumer 3: D, C, A, B. Note, the consumer vectors are typically normalized to equal length in such joint space representations although, under certain data preprocessing conditions, the raw lengths of such vectors can be shown to be proportional to how well each consumer's preferences are recovered by the vector representation. The goal of such an analysis is to simultaneously estimate the vectors and brand coordinates in a given dimensionality that most parsimoniously captures/recovers the empirical preference data. The analysis is repeated for $t = 1, 2, 3, \dots, T$ dimensions and the dimensionality is selected by inspection of t versus a goodness-of-fit statistic (e.g., variance accounted for) that measures how well the model predictions in Equation (1) match the input preference data, given the number of model parameters being estimated. Note, the

cosines of the angles each consumer vector forms with the coordinate axes render information as to the importance of these derived dimensions to that consumer. The isopreference contours for this model in two dimensions for a particular consumer vector (i.e., locations of equal preference) are lines perpendicular to a consumer vector at any point on that vector, since brands located on such lines would project at the same point of predicted preference onto the vector. Thus, it is important to note that this vector model is *not* a distance-based model. Also, one can freely rotate the joint space of vectors and brand points and not change the model predictions (the orthogonal projections of the brand points onto the consumer vectors) or goodness-of-fit results. As noted by Carroll (1980), one of the unattractive features of this vector model is that it assumes that preference changes monotonically with respect to all dimensions. In other words, since a consumer's vector points in the direction of increasing preference or utility, the more of the dimensions in that direction imply greater preference; that

is, *the more the better*. In marketing, this can create conceptual problems depending upon the nature of the underlying dimensions. This assumption may not be realistic for many latent attributes or dimensions underlying brands in a product/service class. For example, it is not clear that consumers prefer infinite amounts of large size and sportiness (assuming those were the two underlying dimensions driving their preferences) in their family car. In addition, it would imply that the optimal positioning of new brands would be out to infinity, which is most often not realistic.

THE SIMPLE UNFOLDING MODEL

Coombs (1950) (unidimensional unfolding) and Bennett and Hays (1960) (multidimensional unfolding) introduced a different type of geometric MDS model for the analysis of such metric preference data called the *simple unfolding model*. Mathematically, the model can

be represented as

$$F(P_{ij})^{-1} = \sqrt{\sum_{t=1}^T (a_{it} - b_{jt})^2} \tag{2}$$

where we use the same notation as that used in the vector model in Equation (1) with some striking differences relating to the nature of how consumers' preferences are represented in this approach. In particular, in the simple unfolding model, both brands and consumers are represented as coordinate points in the derived T -dimensional space. Here, the closer the distance between a consumer and a particular brand, the higher the predicted preference for that particular brand. This, distance is inversely related to preference and that is why one sees an inverse function for preference on the left-hand side of Equation (2) above. Figure 2 illustrates this model in two dimensions with three consumers and four brands. The order of predicted preference

Figure 2 The simple unfolding model.

4 multidimensional scaling of preference data

for Consumer 1 would be B, C, A, D; for Consumer 2 this would be A, D, B, C; and, for Consumer 3 would be C, D, B, A. This geometric model is Euclidean-distance based, and the consumer locations are often called *ideal points* as they reflect the optimal combination of the dimensions for that consumer. Thus, unlike the vector model where higher preference tends off to infinity in the direction of the estimated consumer vector, the simple unfolding model posits highest utility at the ideal point, and preference trails off uniformly in any direction from that ideal point. The further away a brand is from a consumer ideal point, the less preferred that brand is. Here, the isopreference contours in two dimensions are concentric circles around an ideal point since all brand points of fixed radius around the particular brand point would reflect equal preference by this model. Both the brand locations and consumer ideal points are estimated to best recover the empirical preference data. As in the vector model, the analysis is conducted in $t = 1, 2, 3, \dots, T$ dimensions, and the dimensionality is selected in terms of parsimony in contrasting goodness of fit versus the number of model parameters estimated. Like the vector model, one can rotate the joint space configurations and not affect distances. The simple unfolding model also is indeterminate with respect to the origin of the derived joint space. Nonetheless, the simple unfolding model is more appealing to marketers given its finite preference utility assumptions and intuitive underlying Euclidean distance model. Ideal points often represent targets for marketers who try to attempt to position their brands near target segment ideal points (DeSarbo and Rao, 1986). Carroll (1980) also introduced the weighted and general unfolding models which provide for additional forms of individual differences in a multidimensional unfolding context, but these more complex models involve the estimation of many more parameters and successful applications of these more complex unfolding models in the marketing literature are lacking.

As first noted by Carroll (1980), while the vector and ideal point model appear to be quite different geometric representations, one can easily show that the vector model is a special case of the simple ideal point model. If one

were to move an ideal point for any individual consumer further and further out along a fixed line from the origin while holding the brand locations fixed, one ends up with a vector utility model for that consumer in the limit where the ideal point tails off to infinity. The family of concentric circles surrounding that ideal point begins to flatten out and resemble the isopreference lines of the vector model. Thus, there is additional flexibility involved in the simple unfolding model which can accommodate the vector model as a special case. However, despite its greater flexibility and intuitive appeal, the simple unfolding model suffers from frequent degenerate, uninformative solutions where the brand points and consumer ideal points are estimated to be excessively separated from each other (see Borg and Groenen, (2005) for a discussion of attempts to resolve this difficulty).

A MARKETING APPLICATION

In this section, we present a detailed marketing application of these two MDS models using customer consideration-to-buy data from a tracking study conducted in 2002 by a large US automotive consumer research supplier. The study has been conducted semiannually in June and December for over 20 years across several different vehicle segments. It is used to gauge automotive marketing awareness and shopping behavior among vehicle intenders. An *intender* is defined as a prospective buyer who will be “in market” or has plans to purchase a new vehicle within 6–12 months. The surveys used in these tracking studies were conducted among new vehicle intenders and were collected from an automotive consumer panel of more than 600 000 nationally represented households (see DeSarbo, Grewal, and Scott 2008 for additional details). Using a four-point preference response scale (4 – “definitely would consider”, 3 – “probably would consider”, 2 – “probably would not consider”, and 1 – “definitely would not consider”), the respondents rated each brand in terms of their consideration to buy (preference) corresponding to the product segment in which they intend to purchase.

For this illustration, we used the large sports utility vehicle segment which includes

the following 16 brands: Chevy Suburban, Chevy Tahoe, Cadillac Escalade ESV, Cadillac Escalade EXT, Ford Expedition, Ford Excursion, GMC Yukon, GMC Yukon Denali, H1 Hummer, H2 Hummer, Lexus LX470, Lincoln Navigator, Mercedes G-Class, Range Rover, Toyota Land Cruiser, and Toyota Sequoia. Using this product class, we estimate both the vector model and the ideal point (unfolding) model. The data matrix for both models consists of the same individual stated consideration to buy from 278 respondents on the set of 16 large sports utility vehicles SUVs listed above. Thus, this is a two-way dataset of metric brand considerations/preferences where the rows of this data matrix are the 278 consumers and the columns represent the 16 brands.

The vector model results. We first consider the vector model where the goal is to simultaneously estimate the consumer vectors and brand coordinates in a given dimensionality while best recovering the empirical consideration data. Figure 3 shows the resulting configuration in two dimensions with brand locations represented as diamond-shaped points and the consumers as vectors emanating from the origin (we normalize the vectors to equal length for convenience and drop the tails of the vectors in an attempt to reduce the clutter in the figure). With respect to Dimension I (horizontal axis), we see that the GM vehicles are separated from the non-GM vehicles. We thus label this dimension as GM versus non-GM. Dimension II (vertical) represents price with the least expensive vehicles at the top of the axis and increasing in price as

Figure 3 Vector model – SUV application.

6 multidimensional scaling of preference data

you travel down the vertical axis. For instance, the majority of vehicles below the horizontal axis listed for more than \$60 000 whereas the Expedition or Yukon listed in the mid \$30K range at this time. The figure also reveals that brands sharing the same manufacturer are located close together. This means that consumers give these particular brands similar consideration in their purchase plans. Note that four of the GM vehicles are closely located in the first quadrant. Similarly, the two Cadillac Escalades, also GM vehicles, are grouped together, but given their premium pricing they are located with the higher priced vehicles. Other manufacturer groupings include the Ford Expedition and Ford Excursion, Toyota Land Cruiser and Toyota Sequoia, as well as the H1 and H2 Hummers. This particular joint space positioning map is problematic for this set of manufacturers in failing to make their own subset of brands sufficiently distinctive from each other and appealing to different sets of consumers in this particular product segment.

From Figure 3, we also note a heavier concentration of vectors in the top half of the graph near the Chevy and GMC products. We may conclude that for this vehicle

segment, consideration to buy is greatest for the Chevy/GMC brands, followed by the Ford Expedition where we find the next largest concentration of consumer vectors. In this figure, note that a number of consumer vectors are superimposed on one another. This merely represents consumers with very similar consideration-to-buy ratings on all 16 brands. The lower part of Figure 3 shows much less segment consideration for the large luxury sport utility vehicles like the Range Rover and H1 Hummer.

The simple unfolding model results. For the simple unfolding model representation, we first reverse scaled the same input data ($5 - P_{ij}$) given Equation (2). Figure 4 displays the derived two-dimensional joint space spatial map for the simple unfolding or *ideal point* model. Recall that both brands and consumers are represented as points in this two-dimensional space. Here, brands are labeled and represented as diamonds for ease of identification and the 278 consumer are represented by points. The closer a consumer ideal point is to a brand, the higher the consideration to buy for that

Figure 4 Simple unfolding model – SUV application.

particular brand. Figure 4 shows a configuration of brand locations similar to that in Figure 3, and we label these two dimensions accordingly, with Dimension I representing a GM versus non-GM factor, and Dimension II the price. As in Figure 3, the more expensive vehicles are located lower on the vertical axis while the GM vehicles are separated from the non-GM vehicles along the horizontal axis. As indicated above, brands sharing the same manufacturer are located near one another suggesting similar consideration to buy and similar positioning difficulties. The ideal point model shows a clustering of consumer points near the GM vehicles (Yukon, Yukon-Denali, Tahoe, and Suburban). There are also a good number of points in the fourth quadrant, the area between the Suburban and Tahoe and the premium-priced vehicles. Because of the Euclidean distance present in the interpretation of the unfolding model, we might interpret this as potential consumer demand for different varieties of large GM SUV's given the underlying dimensions which define the space.

Discussion. Both Figure 3 (vector model) and Figure 4 (unfolding model) depict a two dimensional joint space with 16 brands and 278 consumers. We find that the two figures are quite similar with respect to their respective brand configurations and interpretation of the underlying dimensions. Since MDS seeks to reveal the underlying structure in data, this result is not surprising given we use the same data matrix to estimate both models. Both representations reveal potential marketing positioning problems where each manufacturer's own brands appear to compete more against one another than against those brands of other manufacturers. More recent work in this area of MDS has attempted to simultaneously perform market segmentation and product

positioning (see LATENT CLASS AND FINITE MIXTURE MODELS) given the same input data as illustrated with these two MDS models (DeSarbo, Manrai, and Manrai, 1994). In such latent structure MDS models, market segments replace individual consumers in such joint space representations.

discriminant analysis for marketing research applications

Fred M. Feinberg

INTRODUCTION

Among marketers' main tasks is *segmentation*: breaking consumers, products, and firms into meaningful groupings. As opposed to a continuum – for example, how much of a particular product a household consumes in a year – data often appear to the marketing analyst in discrete buckets, like “light,” “medium,” and “heavy” users. To aid in conceptual clarity and practical targeting, marketers want to understand and predict which consumers (or products, or firms, etc.) fit into which group. That is, we would like to use a set of variables at our disposal to help explain how, and perhaps why, these groupings come out the way they do, which in turn implies explaining patterns of *group membership*. Other examples abound. For instance, can we: easily distinguish new versus returning customers? explain which of our five stores various customers chose to shop at? understand how contracts get assigned to different countries, or regions in a distribution zone? find some way to entice “loyal” versus “switcher” customer groups? In each of these cases, we have a set of distinct objects – sometimes two (heavy vs light users), sometimes more (which brand was purchased?) – that constitute the *outcome* or the dependent variable. Our goal as marketing researchers is to understand how *predictors* at our disposal relate to that outcome. Just like in ordinary least squares (OLS) regression, these predictor variables can be interval-scaled (or binary, with certain caveats discussed later), but the dependent variable is what statisticians call “discrete” (or “nominal,” “categorical,” “polytomous,” or “multinomial,” depending on context; see MODELS FOR CATEGORICAL DEPENDENT VARIABLES).

And so we seek a tool that operates like ordinary regression in power, ease-of-use, and applicability, but whose goal is to *discriminate* among two or more known groups. As its name suggests, discriminant analysis (DA) is that tool. It builds on a foundation of

ordinary MULTIPLE REGRESSION, and uses some ideas from other topics covered in this volume, like factor analysis (see EXPLORATORY FACTOR ANALYSIS), CLUSTER ANALYSIS, and MANOVA (see ANALYSIS OF VARIANCE AND COVARIANCE; REPEATED MEASURES ANOVA). It also stands in for formal discrete choice models like logistic regression (see LOGIT MODEL), which can perform many of the same tasks, but makes different assumptions about the nature of the data and (unobserved) errors.

A common convention is to distinguish DA, which discriminates between exactly two groups, and multiple discriminant analysis (MDA), which handles more. Because the former is just a special case of the latter, we call them both DA unless clarity is compromised. Because discriminating between two groups is easier, both conceptually and visually, most of our development will deal with that case, branching out to multiple groups later in the article, and building on the two-case setup, for which all terminology is identical.

WHY USE DISCRIMINANT ANALYSIS AT ALL?

Marketing researchers typically wish to use DA to accomplish several primary tasks, each of which we examine in detail. Here is a description of each, followed by a concrete example.

1. *Discrimination*: How can we determine linear combinations of the predictor (independent) variables that help best discriminate among *known* groups (dependent variable)? (“Which variables in our database (past sales, demographics, etc.) best explain which of our customers *did* renew their service contracts in the last year?”)
2. *Classification/Prediction*: Given a new set of data points (individuals, items, units) whose group memberships are *unknown*, how would they be classified into the preestablished groups? (“Can we use the identified variables to predict which customers *will* renew their contracts in the coming year?”)
3. *Verification*: Are there *significant differences* across the various groups in the (predictor variable) profiles of the individuals found

2 discriminant analysis for marketing research applications

in them? (“Does the customer data we pay to collect truly help in distinguishing those who renew from those who do not, or could it be chance alone?”)

4. *Influence*: Which of the predictor variables best account for between-group differences? (“Can we *order* our customer profile variables by how much each helps in separating those who renew from those who do not? Do some fail to help discriminate at all?”)

We see here several different uses for, and subanalyses within, DA. Generally speaking, we want to use known group memberships to estimate “discriminant functions”; use those functions to make predictions; figure out whether the whole model is useful; and, if it is, clarify which parts of it (i.e., predictors) help the most. In this way, DA is like multiple regression, which yields, analogously: a linear function of the “independent” variables; a “prediction” or “fit” for each data point; an overall measure of how well the model is working (F -test); and separate measures for the significance of each variable (t -tests). The only real differences are that DA works with a categorical dependent variable and, when there are more than two groups to distinguish, produces several discriminant functions, not just one. Keeping the correspondence between regression and DA in mind proves helpful in understanding how it operates and in interpreting typical output.

An important consideration in using DA is that group membership must be known, with certainty, for the cases we use to calibrate the discriminant function. It is the analyst’s task to *reproduce* that pattern of membership as closely as possible using the available predictors. This stands in contrast to methods like cluster analysis, which seek to *determine* the best way to group items based on a set of input variables, with no “correct” group memberships to compare with, and methods like MANOVA, which seek to use known group memberships to predict other information about the members of those groups (MANOVA, in fact, is mathematically identical to MDA, and is in some sense DA in reverse). It also stands in contrast to the so-called “interdependence methods,” like factor analysis, which seek to interrelate a group of variables, not

to use them to predict a designated dependent variable.

AN INTRODUCTORY EXAMPLE

To guide our discussion of DA, let us first consider a concrete marketing problem. Firms selling via the web often wish to distinguish between first-time and repeat customers. First-time customers need to be drawn to the site in order for the business to expand and to help spot market trends. Repeat customers are the lifeblood of firms for whom customer “stickiness” – their willingness not to buy from rival retailers who may offer better pricing – is critical. A target firm may also want to know which type of advertising or promotions are especially effective for each group or market segment. So, a key issue is how to best discriminate between these two groups, new and repeat customers.

In our example, let us assume that we have data from a representative day of operations for a multiproduct e-commerce firm, consisting of a number of variables describing customers purchasing at least one item from the website; each customer’s total purchases for that day are recorded, so each appears only once. The dependent variable is whether this was their first purchase or not. We restrict our analysis to variables that would be known to the retailer – those recorded as part of the browsing and purchasing experience – although in many real-world applications other variables, involving survey, behavioral, or complex demographic data might also be available. For the purposes of graphical illustration, we will use just two predictor (independent) variables;

- X_1 = Total dollar amount of purchase (in hundreds; AMT)
- X_2 = Total time spent shopping (in tens of minutes; TIME)

Purists might quibble with the fact that we are treating both variables as interval-scaled, even though they are necessarily positive. Such are the problems in applied research. Rare is the application where all variables neatly conform to the multivariate normality assumption. Experience suggests that the results of DA are broadly

Figure 1 Geometric illustration of discriminant analysis for two groups, using two variables.

robust to this assumption, but we examine visual diagnostics and tests later that will help determine the extent of any problems its violation might cause.

ASSUMPTIONS AND GEOMETRIC FUNDAMENTALS

It is helpful to form a picture of what DA attempts to do, and then translate that picture into symbols. To do so, it is important to know what DA assumes about the structure of the data under consideration. We specify this first for the “two group” problem described above, and then generalize it for MDA. Precise, technical assumptions appear at the end of the article; what follows directly is a geometric and heuristic discussion.

DA’s assumptions are familiar from both regression and, especially, ANOVA. If we have two groups to distinguish, we assume that the predictors (independent variables) have the same multivariate normal distribution *within*

each group. Although this appears to rule out the use of binary predictors, it is usually fine to include a limited number of these as well, even if they do not strictly conform to the model’s assumptions. In simple terms, each group’s distribution differs only by its *mean*; once the mean is subtracted off, each group’s data can be assumed to be drawn from the same normal distribution (bivariate for two predictors; multivariate for more). Graphically, for two variables and two groups (as in our marketing example), this looks like Figure 1.

In Figure 1, the data for both groups appear, superimposed with “80% probability” ellipses; that is, 20% of the points, on average, will fall outside (for more than two predictors, these will be ellipsoids in a higher-dimensional space; 80% was chosen for illustration purposes only). Note that these ellipses are presumed identical in shape, differing only in their mean, or *centroid*. An important point is that, if we assume the within-group data are multivariate normal, then *any* linear combination will be

Table 1 Group summary statistics.

| Groups | Variable | Mean | Std. Dev. | Group Size |
|------------------|-----------|------|-----------|------------|
| Group 1 “Repeat” | X1 (AMT) | 2.64 | 0.759 | 100 |
| | X2 (TIME) | 1.89 | 0.719 | 100 |
| Group 2 “New” | X1 (AMT) | 1.90 | 0.749 | 101 |
| | X2 (TIME) | 2.79 | 0.699 | 101 |
| Total | X1 (AMT) | 2.27 | 0.840 | 201 |
| | X2 (TIME) | 2.34 | 0.838 | 201 |

(univariate) normal. The problem solved by DA is to find the one linear combination that minimizes the “spread” (standard deviation) of this common, within-group univariate normal distribution, relative to the between-group variation (where “variation” retains its usual statistical meaning as related to an appropriate sum-of-squares, corrected for interpredictor correlations, as discussed later). It is not difficult to discern that the linear discriminant function depicted in the graph accomplishes this; the line labeled “discriminant function” crosses the narrowest dimension of the cloud of data points. Put informally, sitting on a line in any other orientation would “see” more spread in the data: for example, the two superimposed normal distributions in the lower left “see” rather little within-group spread; the other superimposed normal, in the lower right, “sees” a great deal of spread. Note that any linear function of the two variables used in the space reduces the dimension of that space down to just one. In this sense, the discriminant function projects the space from multivariate to univariate, giving a single discriminant “score” to each point in each group, and minimizing the ratio of within-group to between-group variation.

Also depicted in Figure 1 is a “separator” line, which optimally classifies the points into the two groups. The classification in this case is not perfect: some points from each group would be classified as being in the other. This separator – which for MDA will be a higher-dimensional hyperplane orthogonal to the linear discriminant function – can also be used to *predict* group memberships for any new points requiring classification. As discussed later, this can be done using *classification functions* for each group.

DISCRIMINANT ANALYSIS FOR NEW VERSUS REPEAT PURCHASE DATA

If we run DA on these data (depicted in Figure 1), we receive a sequence of results that tell us how well model assumptions are met, as well as various estimated quantities pertaining to discrimination. Let us examine selected output of a typical analysis. Before determining the discriminant functions, it is good practice to examine “summary statistics” for the data (Table 1).

Table 1 above tells us the groups are nearly equal in size (100 and 101, respectively); that group centroids appear different (2.64, 1.89 for Group 1; 1.90, 2.79 for Group 2); and that within-group standard deviations are roughly equal for variables $X_1 = \text{AMT}$ (0.759, 0.749) and $X_2 = \text{TIME}$ (0.719, 0.699). It is not entirely surprising that new customers spend, on average, less money (\$190 vs. \$264), but more time (27.9 vs. 18.9 minutes), on the site than repeat customers. Note that the standard deviations are greater for the entire group (0.840 for X_1 , 0.838 for X_2) because these have not been “corrected” by the group centroids, so there is more overall variation. We next test to see whether the means for X_1 and X_2 are the same across groups (Table 2).

These tests, both “Wilks’ Lambda,” have significance levels below 0.0005, suggesting

Table 2 Tests of equality of group means.

| | Wilks’ Lambda | F | df1 | df2 | Significance |
|-----------|------------------|--------|-----|-----|--------------|
| X1 (AMT) | 0.803 | 48.876 | 1 | 199 | 0.000 |
| X2 (TIME) | 0.712 | 80.657 | 1 | 199 | 0.000 |

Table 3 Covariance matrices (before DA).

| Groups | | $X1$ (AMT) | $X2$ (TIME) |
|--------|-------------|------------|-------------|
| 1 | $X1$ (AMT) | 0.577 | 0.230 |
| | $X2$ (TIME) | 0.230 | 0.516 |
| 2 | $X1$ (AMT) | 0.561 | 0.194 |
| | $X2$ (TIME) | 0.194 | 0.489 |
| Total | $X1$ (AMT) | 0.705 | 0.043 |
| | $X2$ (TIME) | 0.043 | 0.702 |

strong differences in the means across groups, and that discrimination should be powerful for these data. Next, we examine the *covariance structure* of the predictor data, both before and after DA is applied.

Table 3 looks at the data before any analysis. The top two sections compare the covariance for the two groups; they appear roughly equal. The lowest section, for the two groups pooled (taken together, or all 201 points), illustrates an interesting phenomenon: the covariance (and correlation) gets very small (0.043). The true correlation structure apparent in the ellipses of Figure 1 only shows up clearly when the groups are analyzed separately, that is, when they are mean-corrected.

Table 4 looks at the data after DA is applied, and a *common* covariance matrix is estimated for the two groups. Note that it appears to “lie between” the covariance matrices for the two groups (in the first table), and is close to an average of them. Finally, the correlation matrix tells us that, once we account for group differences, the correlation in AMT (X_1) and TIME (X_2) is about 0.397, which is sizable. This correlation is automatically accounted for in all “distance” measurements made in DA, as discussed more fully below.

Table 4 Pooled within groups matrices (after DA).

| | | $X1$ (AMT) | $X2$ (TIME) |
|-------------|-------------|------------|-------------|
| Covariance | $X1$ (AMT) | 0.569 | 0.212 |
| | $X2$ (TIME) | 0.212 | 0.502 |
| Correlation | $X1$ (AMT) | 1.000 | 0.397 |
| | $X2$ (TIME) | 0.397 | 1.000 |

Table 5 Test for covariance equality.

| | |
|----------------------|-------|
| Box’s M (F -test) | 0.215 |
| Significance | 0.976 |

It is possible to rigorously test whether the two within-group covariance matrices indicate equality of covariance structure.

This test, Box’s M, is an F -test, which the program assesses automatically as having a p -value of 0.976. Small values of p allow us to reject the null hypothesis of equal covariance matrices. Here, we cannot, meaning this assumption (covariance homogeneity) of DA is reasonable for these data (Table 5).

Next, we wish to determine which variables to include in the analysis (Table 6). The computer offers to do this for us using a *stepwise* procedure, explained more fully later in the article.

This part of the analysis indicates that both variables (X_1 and X_2) should be included in the discriminant function ($p < 0.0005$); apparently, of the two, X_2 should be “entered” first, as it does a better job discriminating than does X_1 , if we could choose just one of them. That both variables should be used here is unsurprising; a quick glance at Figure 1 suggests as much. When there are more groups and more discriminant functions, this part of the analysis – *model selection* or *specification* – can be far more complex.

We now consider the discriminant function itself, and determine how well it helps distinguish the two groups.

We shall examine these tests and table entries in much more detail later. For the time being, the first (Table 7) tells us that the “canonical correlation” is 0.719, meaning that the DA analysis accounts for nearly 72% of the uncorrected variation in the total data. The second (Table 8) tells us that the significance, $p < 0.0005$, is strong; that is, the discriminant function explains a highly significant proportion of the variation in the data. Note that it is possible to have good (i.e., high) values of the correlation and bad (i.e., far from zero) values of p , and vice versa. The first measures the proportion of variation explained, which can be high even in small data sets; the second gives the likelihood this is by chance alone, and reflects how much data has been used in the analysis. In this way, they

Table 6 Determining variables to ‘enter’ the discriminant function.

| Step | Entered | Statistic | Wilks' Lambda: Exact F | | | |
|------|-----------|-----------|------------------------|-----|---------|--------------|
| | | | Statistic | df1 | df2 | Significance |
| 1 | X2 (TIME) | 0.712 | 80.657 | 1 | 199.000 | 0.000 |
| 2 | X1 (AMT) | 0.483 | 105.892 | 2 | 198.000 | 0.000 |

are analogous to the R value and F -test in ordinary multiple regression. We next examine the discriminant function itself (Tables 9 and 10).

Table 9 shows the actual linear discriminant function: $f(X_1, X_2) = (-1.183)X_1 + (1.349)X_2 + (-0.578)$, where X_1 is the amount (in hundreds) and X_2 is the time (in weeks). We need not pay attention to the constant, which is there for technical reasons, much like in ordinary regression (note that, in Figure 1, we have used a different constant to make the graph easy to read, but the principle is the same). What the discriminant function says is that we get the “best” separation of the two groups when we multiply AMT by -1.138 and TIME by 1.349 . Simply put, Group 1 (“Repeat”) figures higher on AMT, and lower on TIME, than Group 2 (“New”). One might reply that this much was obvious from the outset, because the group means are (\$264, 18.9 minutes) for repeat customers, and (\$190, 27.9 minutes) for new customers (recall that our scaling are in hundreds of dollars and tens of minutes). But there are an infinitude of functions that would discriminate these numbers, including a vertical line (that is, $X_1 = \text{AMT}$ is constant) between 1.90 and 2.64, or a horizontal one ($X_2 = \text{TIME}$ is constant). The coefficients ($-1.138, 1.349$) not only distinguish these group means, but provide the *greatest possible discrimination (distance), relative to the remaining variation in the data*. In terms of marketing, if we needed to make a guess about whether a particular customer was a new customer or a repeat customer on the basis of their total purchase (AMT) and duration (TIME) alone, the single best index possible is the discriminant function above. Note that the function separates the group means well, with a value of -1.034 for Group 1 and 1.024 for Group 2. This distance (2.058) is large relative to the spread of the within-group data, which we know has variance of 0.569 for X_1 and 0.502 for X_2 .

For completeness, we include two other sets of quantities closely related to the discriminant function above (Tables 11 and 12).

These are the *standardized* coefficients and the *structure matrix*. The first merely says what the DA function would be if the variables were standardized first (i.e., transformed so that their means are zero and standard deviations one, which is why there is no constant). The second lists the *correlation* between each variable (X_1 and X_2) and the DA function. Note that these are not the same as the standardized coefficients, because X_1 and X_2 are correlated with one another, within-group (with, as we saw earlier, an estimated correlation of 0.397). We will examine the standardized coefficients and structure matrix in more detail later in the article.

Finally, we would like to see how well the model works, in terms of classification, by which we mean the ability to predict which group a customer belongs to based on the amount and time alone. This is assessed in two ways, as shown in Table 13.

There are two matrices here, “original” and “cross-validated.” The first shows that 85.0% of Group 1 and 83.2% of Group 2 cases were correctly classified by the DA analysis. The second recomputes the DA analysis with each of the 201 original cases left out, then reassigns that point based on the new DA coefficients (i.e., via 201 additional DA analyses, each using 200 cases). Although these results are identical here, this will not be the case in general. Overall, just over 84% (169/201) of the cases are correctly classified, which seem quite good relative to random guessing, based on the 100/201 and 101/201 “prior” probabilities, which reflect just over a 50% success rate.

We next present a general discussion of all the diagnostics, assumptions, metrics, and tests in both two-group DA and multigroup MDA.

Table 7 Eigenvalues.

DISCRIMINANT ANALYSIS IN DETAIL

Two group and multiple group linear discriminant functions. When there are two groups, DA is closely related to multiple regression, if we allowed the dependent variable to be dichotomous. That is, the *linear discriminant function* is

$$L = b_0 + b_1X_1 + b_2X_2 + \cdots + b_mX_m \quad (1)$$

where b_0 is a constant and $\{b_1, \dots, b_m\}$ are coefficients for the predictors $\{X_1, \dots, X_m\}$. Variables with the most significant (i.e., largest standardized) coefficients are most useful in group discrimination, via the linear function L .

For more than two groups, the picture is more complex. One could estimate a function like L above to discriminate the first group from all the others, or the last three groups from all the others, or use some other strategy. While this is possible, it is ad hoc, cumbersome, and would require a great deal of forethought from the researcher. Instead, it is far more sensible

to use a function like L to provide the most *overall* discrimination amongst the entire set of groups; then a second function (orthogonal, or statistically uncorrelated, to the first) to account for as much *remaining* discrimination as possible; and then a third; and so on. This logic is analogous to the extraction of successive orthogonal factors in factor analysis, covered elsewhere in this volume (*see* EXPLORATORY FACTOR ANALYSIS). This procedure is computationally equivalent to *canonical correlation analysis*, and provides both the set of successively extracted linear discriminant functions and their *canonical roots* (which are, as in factor analysis, *eigenvalues*). These canonical roots or eigenvalues signify the relative discriminatory power of successive DA functions. Loosely speaking, a DA function with a root (eigenvalue) of 1.5 is 3 times better at overall discrimination than one with a root of 0.5. A useful, scale-free measure of DA function importance is supplied by dividing its root by the sum of all others; these, by construction, must add to 1 (i.e., 100% of the total discriminatory power of the model). The maximum number of discriminant functions is the lesser of {the number of groups minus one, the number of predictor variables}. Note that MDA and (principal components) factor analysis, while related, are *not* mathematically identical: the former maximizes the "distance" between values of the dependent (groupings) variable, whereas the latter maximizes the proportion of total variance accounted for by the factor solution.

Which variables help discriminate?

Interpreting coefficients. A key task in translating computer output to marketing understanding is interpreting the various coefficients provided. All programs provide, if asked, both unstandardized and standardized coefficients, b_i , for every predictor in each discriminant function. Standardized coefficients are generally preferred, as they neutralize scaling differences among the predictors (i.e., an analysis run with X_1 measured in feet versus inches would yield unstandardized coefficients 12 times larger for the first, but the same standardized coefficients). Just like in multiple regression, the larger its (standardized) coefficient, the greater the contribution that variable makes to discriminate among the groups. It is important to note that these coefficients speak *overall* discrimination, that is, among all the groups; they may not do a particularly good job at, say, distinguishing group 2 from group 5. To do that, the researcher can simply compare the *mean* of a particular function across the groups in question, or look at plots of one, two, or even three discriminant function means at the same time (more than this requires visualization of more than three dimensions).

Testing discrimination significance. It is useful to know whether a particular discriminant function in MDA is “significant” in helping to discriminate among the known groupings. *Wilks’ lambda* assesses this significance, based on the eigenvalue for each function. Lambda takes values from 0 to 1, with *lower* values denoting greater discriminatory power. That is, values

near zero suggest group means strongly differ (i.e., the function in question distinguishes among the set of groups), while values near one suggest the group means are about the same (for that function). A significant lambda allows one to reject the null hypothesis that the groups have the same mean discriminant function score, that is, the model does aid in discriminating. There are several other metrics besides Wilks’ lambda to gauge how well DA discriminates between groups, among them being Rao’s V and Mahalanobis’ D-Square, each with an associated significance level. Any of these can be used as criteria for adding and removing variables in stepwise DA. In a similar vein, the *canonical correlation*, R^* , measures how strongly the groups associate with the derived discriminant function. R^* lies between 0 and 1; values near zero indicate a weak relationship, and values near one a strong one. It is also possible to compute an ANOVA table to test the overall adequacy of the DA model. The table yields an *F*-test to assess whether the model with a specific set of predictors discriminates better than a null model (i.e., one with no predictors, just a “grand mean”, or constant).

Interpreting factor structure. Part of the problem in interpreting the (standardized) coefficients is that the predictor variables inevitably intercorrelate. It is possible, for example, that a particular variable appears to have very little influence, because its coefficient is small compared with that of another variable with which it is correlated; this *multicollinearity problem* complicates

Table 13 Classification results.

| | | Group | Predicted Group Membership | | |
|-----------------|-------|-------|----------------------------|------|-------|
| | | | 1 | 2 | Total |
| Original | Count | 1 | 85 | 15 | 100 |
| | | 2 | 17 | 84 | 101 |
| | % | 1 | 85.0 | 15.0 | 100.0 |
| | | 2 | 16.8 | 83.2 | 100.0 |
| Cross-validated | Count | 1 | 85 | 15 | 100 |
| | | 2 | 17 | 84 | 101 |
| | % | 1 | 85.0 | 15.0 | 100.0 |
| | | 2 | 16.8 | 83.2 | 100.0 |

interpretation in all regression-based methods. A distinct, and often more substantively useful, way to determine which variables “drive” a particular discriminant function is to simply compute the correlation between that variable and the function in question. This is called the *factor structure*, after factor analysis (where analogous quantities are called “loadings”). The key point here is that coefficients tell how much a particular predictor explains discrimination *over and above* other predictors in the model; by contrast, factor structure coefficients get at the full effect of each of the predictor variables, in a more “substantively meaningful” way. Therefore, DA coefficients represent *partial* correlations, while structure values represent *full* correlations. Both should be considered in interpreting any DA output. Note as well that the analysis program will provide “significance” levels for all coefficients and structure values; the researcher should strongly consider dropping anything nonsignificant from the final model, once an appropriate significance cutoff (α) is set.

Using DA for classification. Thus far, we have only discussed DA in terms of discrimination among *known* group memberships. Yet, marketing researchers will frequently wish to know how to *predict* which categories new points (e.g., customers, firms, products) fall into. Fortunately, it is a simple matter to use the output from DA to classify such new cases into the preestablished groups. Researchers must always bear in mind that any statistical procedure will typically fit better on the sample on which it was estimated/trained than it will on a new sample. That is, within-sample prediction can “overfit” idiosyncratic elements of training data, and go awry on a new sample with its own idiosyncracies. As such, nonparsimonious models (those including many predictors) can often appear to do a terrific job discriminating the training (calibration) sample, then do surprisingly poor on a new (prediction) sample; models with nearly as many predictors as data points can fit the training sample arbitrarily well, yet say little about prediction samples. Trying out one’s estimated model on different samples is a form of “cross-validation,” and is considered essential in assessing the validity of a particular model. There are several types

of cross-validation available in major statistical programs. A popular option is *leave-one-out* classification, which involves rerunning the DA without a particular case and determining how it would be assigned, and performing this analysis for each case. In this way, it is rather like a *bootstrapping* procedure. It is particularly informative to the researcher, as it can help identify which cases seem to exert strong influence on the discriminant functions and their effectiveness.

Classification functions. Along with coefficients, standardized coefficients, and factor structure values, the DA program will also provide *classification functions*. These are conceptually and computationally distinct from the discriminant functions on which they are based. The purpose of the classification functions is, as one might guess, to classify new cases into the various preestablished groups, with one classification function per group. Deciding on the classification is simple: given a new observation, r , with coordinates $\{X_{1r}, \dots, X_{mr}\}$ for its m predictors, we compute the classification score for each group and assign the observation to the group with the highest score. It is possible to use information about the *a priori* group membership probabilities as well, in line with so-called Bayesian reasoning. For example, if we know from vast experience that 63% of a site’s visitors are male, we should somehow include this information in guessing at a new customer’s gender. The value 0.63 is then the *prior probability*, and the value obtained from the model, conditional on this value, is called the *posterior probability*. Many computer programs allow the researcher to supply this information to be used in all calculations. As a final note, in some situations, a researcher may wish to use *K-nearest neighbor* (KNN) DA. KNN assigns a new case based on the groups to which its k -nearest neighbors belong, and can be a useful adjunct to the standard form of DA.

A word about “distance.” Throughout, we have discussed minimizing and maximizing various “distances,” without precisely defining what this means. Ordinary Euclidean distance, taught in high school geometry, is fine when our predictors are uncorrelated. When they are,

we must instead use the *Mahalanobis distance* instead. When all interpredictor correlations are zero – an extremely unlikely event for real data – then the Mahalanobis distance is the same as the Euclidean distance. When any of these intercorrelations is nonzero, the Mahalanobis distance will take it into account in calculating “distances” between points. When computing, for example, the distance between a particular point and the various group centroids, the Mahalanobis distance is always used. Note that Mahalanobis distance has an appealing scaling based on standard deviations from a group’s centroid: for example, a point with (Mahalanobis) distance of two has a roughly 4.5% probability of belonging to that group, based on the standard z table.

Assessing the predictive accuracy of the model. There are many summary statistical measures to assess the performance of a particular DA model, among them being F -tests (Wilks’ lambda), sums-of-squares, and log-likelihoods. However, these do not speak clearly to managers or retailers. Instead, a simple and evocative measure is the model’s “hit rate”: how often is it right? A version of this that provides more, but equally comprehensible, information, is the “classification matrix,” which, for each group, tells how many times items in that group were correctly classified. The classification matrix goes by many other names (e.g., confusion, assignment, or prediction; matrix or table). Regardless of its title, it is formed by the rows being observed groups and the columns being the predicted ones. That is, it provides quantities for “How often was an item in Group X categorized as being in Group Y ?” This way, a researcher can see if there are groups among which the DA model has particular difficulty classifying. A “good” classification matrix has most of its weight on the diagonal, representing correct predictions. The hit rate, therefore, is merely the proportion of cases appearing on the diagonal. Generally speaking, it is impossible to say what constitutes a “good” or “acceptable” hit rate, as this is so strongly situation-dependent. It may be easy to categorize customers as to their gender, but extremely difficult as to the state they live in.

Stepwise discriminant analysis. A popular way of determining which predictor variables should be included in the final discriminant function(s) is to use a *stepwise* method, which helps determine when to add or remove predictor variables. There are several forms of stepwise DA, and criteria on which they are based. In *forward stepwise* DA, one starts with no predictors in the model. At each “step,” all variables are examined to determine which contributes most to group discrimination. That variable is then included, and the process starts over. In *backward stepwise* DA, one starts with all variables in the model and, at each step, the variable that contributes least to group prediction discrimination is removed. Each process stops when, respectively, adding or removing variables is not justified by an appropriate significance test (as below). If both methods yield the same “final” model, a researcher can feel reasonably confident in having searched the model space (i.e., all possible predictor variable subsets) well. If the methods do *not* yield the same final model, the researcher should carefully examine discrepancies, to determine whether predictor variable intercorrelations were responsible, and make appropriate adjustments, based on the project’s goals and the *meaning* of the predictors.

Adding or removing predictors. Both forward and backward stepwise DA are guided by significance tests, specifically, the “ F to enter” and “ F to remove” values reported by the statistical program. These F values correspond to significance in group discrimination. In short, a variable that aids in group discrimination should be added, and one that does not should be dropped. Researchers must be cautious, however, because they are working with a *sample*, and stepwise procedures can often make variable selections based on chance features of the sample; that is, the training data in the sample may be overfitted. One way to guard against this is to set a higher alpha value for inclusion in the model; this will tend to result in models with fewer predictors. Many statisticians warn against using stepwise regression methods for this reason, but they can be a useful first pass for determining the best DA solution.

SOME ADDITIONAL ISSUES

Use of “dummy” variables. Strictly speaking, dummy variables, because they do not have a multivariate normal distribution, should not be used in DA. In practice, however, they are, and tend not to cause major problems if used judiciously. However, note that the influence of dummy variables cannot be judged by their individual (standardized) coefficients; rather, they must be assessed as a group. A simple way to do this is to run DA both with and without the set of dummies, and to compute the difference in squared (canonical) correlation, just as one compares R^2 values in two (nested) ordinary regressions.

DA versus logistic regression. Logistic regression was developed after DA. It is often used for the same ends, as it entails fewer assumptions and, consequently, fewer violations (specifically, we need not assume that predictor variables are interval-scaled, identically distributed, or are within-group multivariate normal). Furthermore, logistic regression is more robust in practice, in that group sizes need not be roughly equal. As in typical statistical applications, however, DA is more powerful – that is, the chances of not rejecting a false null hypothesis are less – when its (admittedly, many) assumptions are met. Logistic regression is nonetheless considered more “modern,” and many researchers prefer its built-in flexibility.

APPENDIX: ASSUMPTIONS FOR MDA

Categorical dependent variable. The dependent variable falls into “natural” discrete categories, not ones artificially created from underlying (perhaps latent or unknown) variables on another scale, like interval. In practice, the use of MDA is fairly robust to this assumption.

Interval-scaled predictors. All independent variances should be interval-scaled: continuous and without upper or lower bounds. In practice, this is often violated, and binary (e.g., dummies) or multipoint scales (e.g., Likert; *see* ITEMIZED RATING SCALES (LIKERT, SEMANTIC DIFFERENTIAL, AND STAPEL)) can be used

with caution, much like they are in OLS-based multiple regression.

Homogeneous within-group multivariate normality. Within each group, the independent variables should have a similar *structure*: they can, of course, differ in means, but the within-group covariance matrix should be similar (the judged similarity will depend on the relative sizes of the groups; this can be assessed visually, via histograms of frequency distributions, or via formal tests, notably Box’s M). DA can still be used if this is moderately violated, but extreme outliers should always be scrutinized carefully. Note that this multivariate distribution cannot be *degenerate*, which will occur if one independent variable is nearly a linear combination of others, causing “conditioning” problems.

Independence of observations and of errors. The values for any data “point” cannot offer information about any other. This means that, in consumer purchase data (for example), we cannot have some consumers appearing more than once, which could induce various correlations. All errors (distances) are independently and identically distributed (as a univariate normal, with zero mean and an estimated standard deviation).

Model specification. The correct predictor variables have been entered into the model. Note that, if these are substantially intercorrelated, adding or removing variables can affect coefficient values and their significance levels.

Uncorrelated means and variance. A serious problem occurs with the accuracy of significance tests if predictor means are correlated with predictor standard deviations across groups. This can happen in practice if there are even a few extreme outliers; these can inflate the estimated within-group variances and, to a lesser extent, the pooled variance estimates. In such cases, outliers need to be examined and, if justified, removed.

Sample and group sizes. Various requirements dictate when a solution is possible, but these can be extreme in practice, and rules-of-thumb are better guides for the researcher. Strictly

speaking: each group must have at least two points (so that a centroid and variance can be computed); each independent variable has nonzero variation in each group; the maximum number of predictors is the number of data points, minus two; the maximum number of discriminant functions is the minimum of {the number of groups minus one, the number of variables in the analysis}. In practice: no group size should be more than 10 times greater than any other; there should be at least 5 times as many data points as predictor variables; each group should have more than 10 cases (but 20 is preferred, especially as the number of predictors grows). Researchers must bear in mind that these rules do *not* come from theory, but from vast experience with using the method on real and simulated data. In this sense, they are “best practices,” and deviations are inevitable in applied research.

multiple regression

Sangkil Moon

INTRODUCTION

Let us say that a marketing researcher wants to learn about the type of customers who want to buy an iPod touch (32GB for \$399). For the analysis task, probably, the researcher will look at potential buyers' demographic information (e.g., gender, age, income), lifestyle information (e.g., How often do you listen to music while you are on the go? Do you usually buy new high-tech products earlier than your friends?), and preferences for the MP3 player product (e.g., How important is the video function on the MP3 player to you? Do you intend to buy the iPod touch within the next six months?) The researcher can collect such information from potential customers using a survey method. Then, everything is put together for a *multiple regression* analysis to describe what type of customers are likely to buy iPod touch (the dependent variable) using the above-mentioned information (multiple independent variables). Thus, the power of the multiple regression analysis technique lies in effectively describing or predicting a focal concept as the single dependent variable (e.g., purchase intention based on a 10-point scale) using other relevant information as independent variables.

Since this regression technique describes the relationships between the dependent variable and the chosen multiple independent variables, it goes beyond simple descriptive analyses such as obtaining averages or frequency tables (*see* FREQUENCY DISTRIBUTION) of variables of interest. From a marketing practitioner's perspective, it would be much more effective to develop actionable marketing strategies based on an understanding of the relationships identified from a multiple regression analysis than simply examining multiple individual variables separately. Certainly, car dealers need to learn how their potential customers would react (dependent variable) to car price decreases (independent variable) in an extreme economic recession. Therefore, the main purpose of this article is to provide a general and basic overview of multiple regression analysis as a practically

useful statistical technique for solving real-world marketing research problems. Since multiple regression is a standard procedure in various statistical package software programs such as SAS (along with the Enterprise Guide interface, www.sas.com), SPSS (www.spss.com), and Minitab (www.minitab.com), the essay focuses on conceptual and intuitive aspects of this statistical methodology along with its applications in marketing research.

BASICS OF MULTIPLE REGRESSION

Multiple regression analysis is a statistical technique that can be used to analyze the relationship between a single dependent variable and multiple independent variables. The objective of multiple regression analysis is to use the independent variables that are known to predict the single dependent variable selected by the researcher (Hair *et al.*, 2006). A simplified case of this multiple regression analysis is simple regression analysis that has only one independent variable explaining the dependent variable. However, this simple regression analysis is hardly useful for practical marketing research because there are always multiple factors (e.g., demographics, lifestyle, product preferences) that explain the central concept (e.g., purchase intention). Even so, we learn about useful and realistic multiple regression based on the concept and structure of simple regression (or bivariate regression, Burns and Bush, 2006; McDaniel and Gates, 2008) that focuses on the relationship between the dependent variable and a single independent variable because conceptually multiple regression extends simple regression to multiple relationships between the dependent variable and each of the multiple independent variables.

Formally, we can express the multiple regression model equation as follows:

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_k X_k + \varepsilon \quad (1)$$

where Y is the dependent variable (response variable or criterion variable), X 's are k independent variables (or explanatory variables or predictor variables), β 's are k parameters to be estimated, and ε is a disturbance (or error) term. In applying this multiple regression technique to

2 multiple regression

solve practical marketing problems, it is important to understand the properties of each term in this equation. First, both Y and X are obtained from data and, are therefore, *known* variables. For instance, in a survey data context, each variable, whether dependent or independent, can directly come from each appropriate research question in the survey questionnaire. The dependent variable, however, must be a continuous variable (e.g., length, price, sales, customer satisfaction on a 10-point scale) because the statistical model is a *linear* regression as opposed to binary or multinomial logit regression (see MODELS FOR CATEGORICAL DEPENDENT VARIABLES) that can take categorical variables as its dependent variable. For instance, if the problem is one of consumers' choosing their favorite brands in some product category, the logit regression model is used as opposed to the linear regression model because the dependent variable is categorical (e.g., brand alternatives). By contrast, if the product sales is used as the dependent variable, the linear regression is used as opposed to the logit regression because the dependent variable is continuous (e.g., sales in dollar amounts) (Feinberg, Kinnear, and Taylor, 2008). By contrast, we can use both continuous and categorical variables as independent variables in multiple regression but need to reorganize the regression equation in such a way that we identify each category in the categorical variable as a separate binary independent variable with one of the categories as the reference (or base) category. These categorical independent variables are called *dummy variables* and explained in more detail in the section Dummy Variables, later in this article. The linear regression model assumes that ε , the disturbance term, follows a normal distribution, which makes the regression model statistically powerful and convenient.

Finally, β 's are unknown parameters and need to be estimated by minimizing the sum of the squared errors expressed in Equation 2,

$$\begin{aligned} &\text{Sum of squared errors (SSE)} \\ &= \text{Min} \sum (Y - \hat{Y})^2 \quad (2) \end{aligned}$$

$$\hat{Y} = b_0 + b_1X_1 + b_2X_2 + \dots + b_nX_n \quad (3)$$

where b 's are estimates for β 's. This estimation method is called the *ordinary least squares (OLS)*

method. Conceptually, the estimation rule amounts to finding the best linear line that minimizes the errors between the estimated regression line and a collection of the actually observed data points.

As one can logically expect, not all the independent variables initially selected by the researcher would influence the dependent variable *significantly*. Therefore, the research needs to "trim off" independent variables that do not have a legitimate influence on the dependent variable. Theoretically, the statistical significance level that is used for the cutoff level for the trimming-off job can range from 0 to 100% and set by the researcher based on his or her substantive goals. And yet, the most common cutoff significance levels are 1, 5, and 10%. The lower the statistical significance level, the stricter is the test. In other words, a lower significance level results in fewer significant independent variables. To test such a *statistical significance* of each independent variable, we compute the p value for the independent variable, which also ranges from 0 to 100%. The p value measures the confidence that the analyst can have in the estimated value for the intercept or each independent variable in the regression model. The lower the p value for the independent variable is, the more significant is its estimated value. Then, the p value is compared with the predetermined cutoff significance level. If the p value for the particular independent variable is smaller than the predetermined significance level, the variable is determined to be statistically significant. (These p values are automatically reported along with parameter estimates on a statistical program.) The procedure of selecting a proper regression model with only significant independent variables is called *STEPWISE REGRESSION*. There are three approaches for conducting the stepwise regression – (i) forward selection, (ii) backward elimination, and (iii) hybrid approach (combining both forward selection and backward elimination). *Statistical significance* is required for a relationship to have validity, but statistical significance without theoretical support (*practical significance*) does not support validity. Basically, practical significance means that the result makes sense conceptually and theoretically but cannot be

tested statistically in a straightforward manner unlike statistical significance. To summarize, before we apply the results of any regression analysis to a real-world case, we need to confirm both types of significance.

INTERPRETING REGRESSION PARAMETER ESTIMATES

b_i is an estimate for parameter β_i . More specifically, b_i is our best guess for the *unknown* true parameter value β_i . The estimate measures both the *direction* and *size* of the impact of X_i on Y while holding all the other predictors constant. For example, let us say Y = total brand sales (in dollars) and X_1 = brand price (in dollars) along with other independent variables such as brand promotion frequency and brand consumer ratings being used. We obtain $b_1 = -500$ from our regression. What does that mean? First, the negative sign indicates the brand price increase has a negative influence on the sales of the brand (impact direction). Second, as the brand price is increased by \$1, the total brand sales decreases by \$500 (impact size). This can be very useful information for marketers because they can tell how much sales they will lose when they increase the price by a certain amount. There is, however, a caveat in using this kind of interpretation; the regression result is valid only within the observed ranges of the dependent and independent variables based on the linear relationship taken by the model. Specifically, beyond the ranges used in the data, the estimated impact direction and size can be misleading or false. Moreover, the actual relationship between the dependent variable and the independent variable may not be linear, which is not captured in linear multiple regression in a straightforward manner. On the other hand, the parameter estimate for the intercept (b_0) indicates the value of the dependent variable when all the independent variables take the value 0.

It should also be stressed that the estimates are scale dependent, which means that the scales used by the independent variable and the dependent variable can change the size of the estimate, while the actual relationship remains the same. For instance, if we change the scale of X_1 (brand price) from dollars to cents, b_1 becomes -5 from -500 , while we maintain the scale of the

dependent variable (unit dollar). This change means that as the brand price increases by 1 cent, the total brand sales decreases by \$5. In brief, even though the estimate value changed significantly, its real meaning and interpretation should remain the same since the change is only a reflection of a changed scale. Lastly, we often see that the researcher draws a causal relationship based on his or her regression analysis but it is a general understanding that regression alone does not prove any causal relationships.

The variations in variable scales and different variabilities across variables make a direct comparison of multiple independent variables problematic and challenging. Standardization converts each variable to a common scale and variability, the most common being a mean of zero and standard deviation of one. With this approach, we make sure that all variables are comparable on the same scale. The advantage is that it eliminates the problem of dealing with different units of measurement and thus reflects the relative impact on the dependent variable of a change in one standard deviation in each variable. Although this variable standardization allows the researcher to compare the independent variables on a level playing field, it can cause more problems in interpretation and is also limited in its practical uses. For instance, what is the meaning of one standard deviation increase in household income (X_1) as an independent variable that influences the customer's intention to purchase an iPod touch (Y) in comparison with one standard deviation increase in the product price (X_2)? First, the two independent variables are not quite comparable as marketing tools. Second, the meaning of one standard deviation is less clear than the meaning of one dollar as the unit of both variables.

DUMMY VARIABLES

It was mentioned above that, in multiple regression, whereas the dependent variable should be continuous, the independent variables can be continuous or categorical. In treating categorical independent variables, the researcher needs to code binary dummy variables differently from continuous variables in his or her regression analysis. In the regression data matrix, each row takes one observation of the analysis unit (e.g.,

survey respondent, client, firm), whereas each column takes one conceptual construct that can be an independent or dependent variable (e.g., each research question in a survey, each demographic variable). Continuous independent and dependent variables can take their own value, whereas each categorical variable must be set up differently into two or more dummy variables. If the categorical variable has only two categories (e.g., gender with female and male, yes–no question), one of the categories (e.g., male) can be coded as 0 arbitrarily and the other (e.g., female) can be 1, again arbitrarily. Then, the positive sign of its parameter estimate indicates that category 1 (e.g., male) has a positive relationship with the dependent variable against category 0 (e.g., female) as the reference or base category. In the same way, its negative sign indicates category 1 has a negative relationship with the dependent variable. Thus, the dummy variable can only be interpreted in relation to its reference category. When the categorical variable has more than two categories (e.g., three agents in online travel businesses), the coding scheme becomes more complicated by taking $c-1$ variable columns where c is the number of categories in the original variable. The number of dummy variables is one smaller than c because the reference category does not appear in the data matrix. More details on the dummy variable can be found in Churchill and Iacobucci (2005).

HOW TO CHOOSE RELEVANT INDEPENDENT VARIABLES?

The researcher wants to evaluate how good the multiple regression model specified and estimated is. Model specification indicates what independent variables are used to explain or predict the dependent variable of interest. There are various aspects of the model the researcher needs to evaluate to determine how good the model is.

One of such diagnostic measures is the coefficient of determination (R^2). R^2 is used to measure the proportion of the variance of the dependent variable explained by the set of independent variables used and ranges from 0 to 1. The higher the coefficient, the better the model is in terms of data fitting with 1 indicating the estimated regression line perfectly fits the

data. There is no clear cutoff level in R^2 to accept or reject the estimated regression model even though novices quite often tend to use this value as the all-purpose diagnostic measure in evaluating the model under investigation. This can be misleading because the R^2 measure also depends on the sample size in association with the number of parameters being estimated. For example, a multiple regression with five predictors estimated on six data points will produce the R^2 of value 1 regardless of data or predictors. Importantly, however, if the measure is too low, it means the model, particularly the independent variables used, does not explain the dependent variable properly, which should caution the researcher to change the regression model by finding other independent variables that can explain the dependent variable better. It should be noted that the addition of more independent variables will always increase the R^2 value, even if nonsignificant ones are added. By contrast, with the adjusted coefficient of determination (adjusted R^2), adding nonsignificant independent variables just to increase R^2 is discounted in a systematic manner. In other words, when the researcher adds another independent variable, the adjusted R^2 will balance a positive factor (added explained variance by the added variable) with a negative factor (penalty for having another independent variable). Therefore, when we add another independent variable to our regression model, adjusted R^2 can go either way unlike R^2 . For this reason, adjusted R^2 can be effectively used to determine whether the researcher needs to add a particular independent variable (Hair *et al.*, 2006).

Any estimation method for multiple regression including the above-mentioned OLS method requires that the chosen model is not misspecified. Misspecification usually concerns the notion that the maintained assumptions for the unobserved error variable ε are violated or that the functional form, which is linear, is inappropriate (Franses and Paap, 2005). The most problematic issue in independent variable selection is specification error, which concerns the inclusion of irrelevant variables in or the omission of relevant variables from the set of independent variables. We can find out whether a model is misspecified only after we conduct diagnostics testing for a variety

of theoretically possible models including the coefficient of determination test. As a rule of thumb, when it is unclear, the researcher would consider including potentially irrelevant variables rather than possibly omitting relevant variables. From a broad perspective, finding the properly specified multiple regression requires a lot of trial and error with both statistical skills and conceptual reasoning. Besides, this misspecification error concern related to the assumptions for the unobserved error variable in linear regression makes the analyst transform some limited continuous dependent variables such as the sales variable that can take only a positive value. In this example, since the limited range of the dependent variable can skew the distribution of the unobserved error variable in an undesirable fashion, the analyst would need to take the log value of the original sales variable as a transformed dependent variable. To specifically transform the dependent variable a careful inspection of the residuals ($Y - \hat{Y}$) defined by Equations 1–3 is required.

In determining the set of independent variables, the researcher also would need to check MULTICOLLINEARITY. Multicollinearity refers to the correlation among independent variables. Generally, the correlation indicates the relationship between two variables, whether positive or negative, which is commonly measured by Pearson's product-moment coefficient of correlation (*see* PRODUCT MOMENT CORRELATION) (Glass and Hopkins, 1984). For instance, in explaining consumers' general movie ratings (dependent variable), their evaluations of the subcategories of acting and directing (two independent variables) can be highly correlated. If the correlation is too high, we need to drop the inferior of the two variables from the independent variable set because the two variables play about the same role in explaining the dependent variable. Formally speaking, the impact of multicollinearity is to reduce any single independent variable's predictive power by the extent to which it is associated with the other independent variables (Hair *et al.*, 2006). To maximize the prediction from a given number of independent variables, the researcher should look for independent variables that have low multicollinearity with the other independent variables but also have high correlations with

the dependent variable. To formally assess multicollinearity, we can use the tolerance measure expressing the amount of variability of the selected independent variable not explained by the other independent variables; this ranges from 0 to 100%. A high tolerance value means a small degree of multicollinearity, which is good for the model. A common but rough cutoff threshold is a tolerance value of 10%.

The most appropriate empirical validation approach is to test the regression model on a new sample drawn from the general population (validation sample or holdout sample) against the sample used for estimation (estimation sample or calibration sample). When we obtain similar results from both samples, we can be more confident that the regression estimates are valid. For the task, the researcher needs to set aside a proportion of the original sample as the validation sample that will not be used for the estimation purpose. One downside to this validation approach is it makes the estimation sample size smaller, which reduces the statistical power of the estimation approach in various ways. If the researcher has a large sample, this would not be a problem. A larger sample, however, increases the research budget.

APPLICATIONS OF MULTIPLE REGRESSION IN MARKETING RESEARCH

Multiple regression can be applied to cases where the researcher is interested in the relationships between a central concept (e.g., customers' purchase intention) and other concepts or measures (e.g., age, product rating, previous purchase experience) that can potentially explain the central concept. The analysis technique has an extremely wide applicability and has been applied in most disciplines including marketing research. Most marketing research books introduce the technique in varying degrees of detail with practical application examples. Several such examples from some popular marketing research textbooks are briefly introduced here.

First, Parasuraman, Grewal, and Krishnan (2004) used an example of a school librarian who is eager to increase the number of students borrowing books from the library. They indicated that she can use multiple regression to

provide persuasive evidence that demonstrates how increased borrowing of books can benefit students by explaining students' GPAs (dependent variable) with number of books borrowed (independent variable). Second, Cooper and Schindler (2006) introduced an example of applied multiple regression to evaluate the key drivers of customer usage for mail (dependent variable). In the analysis, cost, speed, security, and reliability of mail turned out to be significant predictors of mail usage. Third, Hair *et al.* (2008) provided a regression example, where the researcher applies multiple regression to examine the relationship between perceptions of the food in the restaurant (independent variables) and overall customer satisfaction (dependent variables). Food perceptions included customer ratings of the restaurant on fresh food, food taste, and food temperature. Lastly, Malhotra (2009) discussed an example of Wendy's customers' patronage likelihood (dependent variable) in multiple regression. Customer ratings of Wendy's on menu selection, quality, service, value, and location convenience were used as independent variables to explain its customers' patronage likelihood.

WARNINGS IN USING MULTIPLE REGRESSION

As shown everywhere, including real-world marketing research, multiple regression is one of the most popular and powerful tools from among numerous common statistical analysis tools such as correlation and analysis of variance (ANOVA). As in any analysis tool, however, it has its limitations, which should be considered before the researcher decides to apply the technique to his or her own problem. Several common caveats are described here.

First, multiple regression basically captures only a *linear* relationship between each independent variable and the dependent variable as a type of *linear* regression. Even though the linear relationship is a fundamental assumption, it is possible to capture some limited types of curvilinear relationships by transforming or extending original variables. For instance, the theory we want to test says that there is an inverted U relationship in advertising spending (independent variable X_1) on consumers' brand image (dependent variable). In this case, the

inverted U relationship means that advertising spending enhances consumers' brand image only to a certain level of advertising when the advertisement can raise consumers' awareness of and familiarity with the advertised brand. Beyond the saturation level, however, the same advertisement can do more harm than good to its brand image because too much advertising can elicit negative emotional reactions (e.g., boredom, fatigue) in consumers. To test the theory, we can add the quadratic term of the original linear variable (independent variable X_1^2) to the regression equation while still keeping the other variables. The combination of both parameter estimates will determine whether there is an inverted U relationship between advertising spending and consumers' brand image. More general curvilinear relationships can be captured by extending the original independent variable to a higher degree of polynomial terms (e.g., X_1^3 , X_1^4).

Second, the ranges of data on the dependent and independent variables influence how widely the regression results can be applied (Parasuraman, Grewal, and Krishnan, 2004). In principle, the regression results apply only within the range of the data used for estimation. In the above example on the influence of advertising spending on brand image, let us say the collected data covered only the range between \$1 million and \$10 million. Then, we cannot directly apply the parameter estimate result to the case of \$20 million, which is beyond the range of the data used.

Third, the relationship that is identified as statistically significant in regression does not prove a cause-and-effect association (*see CAUSAL RESEARCH*). The statistically significant relationship in regression simply indicates an association between the independent and dependent variables without any direction. In a simple linear regression, if we change the roles of the independent and dependent variables, the regression will generate similar results because the method itself is blind to the direction of the impact. Generally, the cause-and-effect association cannot be proved by statistical methods alone. The researcher should use his or her own reasoning and intuitions based on solid theories and practical examples to prove a causal relationship.

structural equation modeling

Hans Baumgartner

INTRODUCTION

Structural equation modeling (SEM) with latent variables, also known as *latent variable path analysis*, is a technique for investigating relationships between latent (unobserved) variables or constructs that are measured by multiple manifest (observed) variables or indicators. Special cases are CONFIRMATORY FACTOR ANALYSIS (see EXPLORATORY FACTOR ANALYSIS), in which no directional relationships between latent variables (factors) are specified, and manifest variable path analysis, in which directional relationships between observed variables are modeled. As an illustration, consider the model shown in Figure 1. This model is an attempt to explain consumers' usage of coupons for grocery shopping via a number of antecedent constructs. According to the model, actual coupon usage is a function of consumers' intentions to use coupons, which in turn depend on their attitudes toward using coupons. Attitudes are influenced by three types of beliefs about the consequences of using coupons: rewards (positive consequences associated with coupon usage such as saving money on the grocery bill); inconveniences (one type of negative consequence associated with coupon usage such as the time and effort required to use coupons); and encumbrances (another type of negative consequence associated with coupon usage such as the need to buy nonpreferred brands in order to take advantage of coupon offers).

This simple model illustrates two of the major advantages of SEM. First, SEM makes it possible to study complex patterns of relationships among the constructs in one's model in an integrative fashion. If regression analysis (see MULTIPLE REGRESSION) were used to analyze the model in Figure 1, one would have to estimate three different regressions, and it would be quite cumbersome to show that attitudes and intentions mediate the effects of beliefs on coupon usage (i.e., that there are no direct effects of beliefs on intentions and coupon usage). In contrast, all relationships

among model constructs can be investigated simultaneously using SEM, and it is straightforward to examine different forms of mediation in complex multistage models. Furthermore, tests of overall model fit are available, which indicate how well the specified model represents the data. Second, constructs such as beliefs, attitudes, and intentions are not directly observable. Using single-item measures to assess the constructs of interest (e.g., asking people whether their attitude toward using coupons is favorable or unfavorable) does not do justice to even relatively simple constructs such as coupon attitudes (the situation becomes more problematic when a construct is more abstract and when it has many facets), and combining multiple measures into averages is ad hoc and makes assumptions that cannot be verified. Furthermore, observed variables always contain error, both random and systematic, and this measurement error has to be taken into account in the analysis because it can have serious distorting influences on investigations of relationships between the constructs in the model. Although SEM is not a panacea for these problems, it encourages researchers to think more explicitly about measurement error, enables assessment of the quality of construct measurement (see VALIDITY AND RELIABILITY), and facilitates the study of structural relationships between constructs in the presence of measurement error.

In this article, we provide an overview of SEM. The presentation is organized around the steps involved in using SEM for theory testing: model specification; preliminary data analysis; model estimation; overall model evaluation; model modification; and model interpretation (Bagozzi and Baumgartner, 1994; Baumgartner and Homburg, 1996). The article concludes with a brief discussion of more advanced uses of SEM and recent developments.

MODEL SPECIFICATION

Graphical model specification. Models can be specified graphically or algebraically, but we focus on graphical specification, because many researchers find it more revealing. Figure 2 shows the graphical specification of a particular version of the model in Figure 1, assuming that two indicators each are available to measure

Figure 1 Theoretical model of the antecedents of coupon usage.

rewards, inconveniences, and intentions, three indicators to assess encumbrances, and four indicators to capture attitudes. Coupon usage, although shown as a latent variable, is actually treated as an observed variable. Latent variables that are of theoretical interest are shown as ellipses (or sometimes as circles). Attitudes, intentions, and coupon usage are referred to as *endogenous latent variables* (denoted by the Greek symbol η) because the model is designed to explain the variation in these variables. Rewards, inconveniences, and encumbrances are called *exogenous latent variables* (denoted by ξ) because they are not explained within the context of the model. The exogenous latent variables are usually allowed to covary freely, and these covariances are shown as double-headed arrows (denoted by φ_{ij}). The relationships of primary theoretical interest are the effects of the exogenous variables on the endogenous variables (denoted by γ) and the effects of the endogenous variables on each other (denoted by β). For example, γ_{11} refers to the effect of rewards on attitudes, and β_{21} to the effect of attitudes on intentions. Associated with each endogenous latent variable is an error term (error in equation or equation disturbance, denoted by ζ), because it cannot be expected that the antecedents of the latent variable can explain it completely. Arrows that emanate from and point to the same variable are variances, and the variances of the ξ 's and ζ 's are called φ_{ii} and ψ_{ii} , respectively (the ζ 's are assumed to be uncorrelated in the present case, although that is

not always necessary). The relationships among the exogenous and endogenous latent variables shown as ellipses constitute the so-called *latent variable model* (sometimes called the *structural model*), which represents the theoretical model studied in the research.

To examine the theoretical model empirically, each latent variable of interest has to have at least one observed measure. The indicators of the exogenous (endogenous) variables are called x (y), and by convention they are enclosed in rectangles (or squares). The coefficients relating the observed variables to their underlying latent variables (so-called factor loadings) are denoted by λ^x and λ^y . The error terms (errors in variables, unique factors) associated with the x 's and y 's are called δ and ε , respectively, and their variances are denoted by θ^δ and θ^ε . In the present case, the error terms were specified to be uncorrelated, but this assumption can be relaxed. The model linking the exogenous and endogenous latent variables to their observed measures is called the *measurement model*.

The model in Figure 2 is a complete specification of the structural equation model of interest, assuming that all relationships between variables are linear. The model contains five types of parameters: the factor loadings (λ^x and λ^y); the measurement error (unique factor) variances (θ^δ and θ^ε); the variances and covariances of the exogenous latent variables (φ); the latent variable model coefficients (γ and β); and the (co)variances of the errors in equations (ψ).

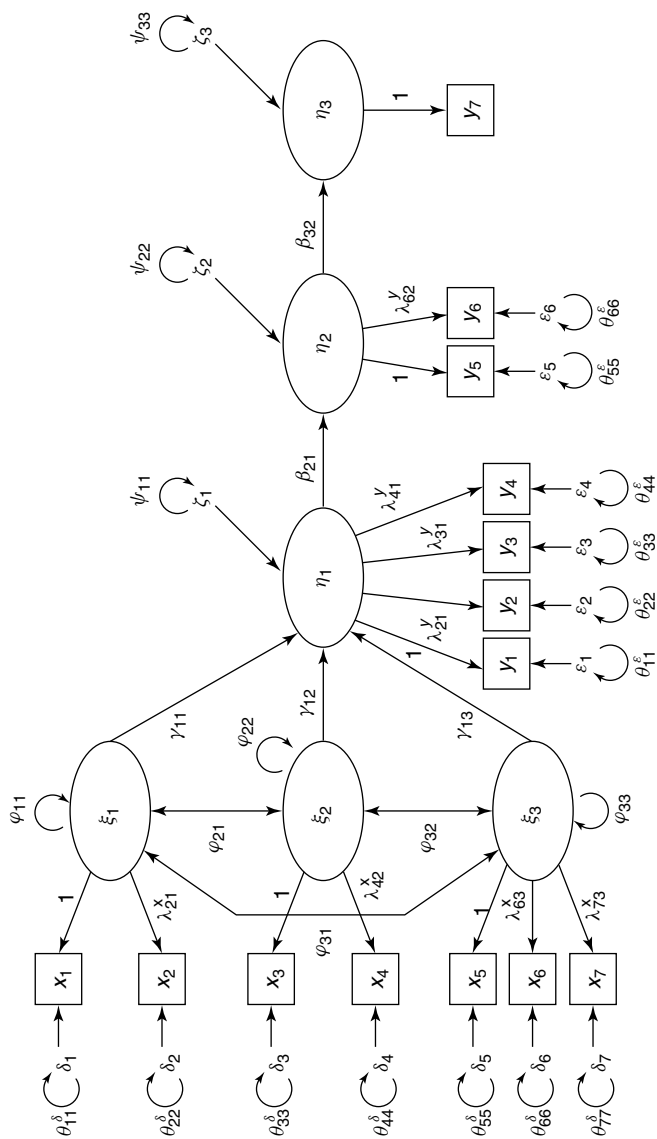

Figure 2 A structural equation model of coupon usage.

4 structural equation modeling

Model identification. For the model to be meaningful, it has to be identified. This means that all parameters in the model are uniquely determined so that the conclusions derived from the analysis are not arbitrary. As a first step, the scale of the latent variables has to be fixed (since the scale in which they are measured cannot be observed directly). One way to do this is to set one loading per latent variable to 1, as shown in Figure 2. In addition, the coefficients relating the error terms (both measurement errors and errors in equations) to observed or latent variables are set to 1 (not shown explicitly in Figure 2 because it is always done by convention). Furthermore, if there is only a single indicator, as in the case of coupon usage, measurement error is usually ignored and the error (unique) variance is set to 0 (another possibility is to assume a certain amount of error variance, preferably based on prior research).

A necessary requirement for identification is that the number of parameters to be estimated should not be greater than the number of unique variances and covariances among the observed variables. For the model in Figure 2, 35 parameters have to be estimated, and there are 105 unique elements in the observed covariance matrix. Therefore, the model has 70 degrees of freedom and the necessary condition for identification is satisfied (since the number of degrees of freedom is nonnegative).

Unfortunately, this simple rule does not guarantee identification. For certain types of models, it is easy to check identification (see Bollen (1989), for an extended discussion), but in general identification is a nontrivial issue. For general structural equation models consisting of both measurement and latent variable models the so-called two-step rule (which is sufficient but not necessary) is often applied. In the first step, the researcher tries to ascertain that a measurement model in which no restrictions on the latent variable model are imposed and all covariances between (exogenous, endogenous) latent variables are freely estimated is identified. If there are at least two indicators per construct, each indicator loads on one and only one construct, the measurement error terms are uncorrelated, and the constructs are allowed to freely correlate, the measurement model is identified. Even if a construct is measured

by a single indicator, as long as the error variance is fixed to a certain value (usually 0, in which case the latent variable is really an observed variable), the model is identified. Using these guidelines, the measurement model corresponding to Figure 2 is identified (with 63 degrees of freedom).

Once the model in the first step is shown to be identified, the exogenous and endogenous latent variables can be treated as observed and the task in the second step is to show that the latent variable model is identified. If the model is recursive (i.e., the matrix containing the β coefficients is subdiagonal, which means there are no reciprocal paths or feedback loops so that latent variables later in the sequence do not influence latent variables earlier in the sequence, and the errors in equations are uncorrelated), the latent variable model is identified. It can be checked that the model in Figure 2 is recursive and therefore identified. If the model is nonrecursive, other rules, such as the rank rule sometimes used to identify systems of simultaneous equations, can be employed.

At times, it is too difficult to show identification explicitly and in that case one may have to rely on the computer program used to flag a nonidentified model. A useful strategy is to start with a simpler model that is known to be identified and to then complicate it by introducing, one by one, the additional parameters to arrive at the desired specification, provided the modification indices associated with the added parameters are nonzero (see the discussion of model modification later in the chapter).

Measurement model specification issues. In Figure 2, it is assumed that the observed variables are functions (or manifestations) of the latent variables. This is called a *reflective measurement model specification*. If an indicator is specified as reflective (i.e., as an *effect indicator*), one assumes that the different indicators of a construct are interchangeable, correlated with each other, and contaminated by measurement error. It is not always meaningful to regard indicators as manifestations of an underlying latent variable. Sometimes, it is more appropriate to conceptualize a given set of indicators as defining characteristics of a construct, in which case the latent variable depends on its

indicators. This is called a *formative measurement model specification*. Formative indicators (also called *cause indicators*) are not interchangeable, need not be correlated, and are usually assumed to contain no measurement error. Since statistical means of trying to distinguish between reflective and formative measurement models are of limited usefulness, the decision whether indicators should be modeled as reflective or formative has to be made based on a conceptual analysis of the items in question. The issue is important because research shows that incorrect specification of the measurement model can lead to significant bias in model parameters (see Diamantopoulos, Riefler, and Roth (2008), for a recent review and additional references). Although indicators should not be specified as reflective when they are not (e.g., satisfaction with different aspects of a job as measures of overall job satisfaction), there are many unresolved issues in formative measurement models, which makes their routine use problematic.

Another issue that has to be considered carefully is how many indicators of each latent variable should be included in the model and how these indicators should be related to the latent variable. In general, it is better to have more rather than fewer indicators per construct, but there are practical constraints on how many items can be put in a questionnaire. Furthermore, including too many individual indicators in a model might make the model too complex, and it is also difficult to get acceptable overall model fits when there are too many indicators per construct. An alternative is to use item parcels, where subsets of individual items are averaged and then used as (multiple) indicators in the model. This is acceptable if the items that are combined are known to be unidimensional (i.e., form a homogenous set), or if items measuring the same facet of a multidimensional construct are combined. If the factor structure of a set of measures is poorly understood, parceling is not a good idea (see Bandalos and Finney (2001), for additional discussion of item parceling).

Latent variable model specification issues. It is generally much more informative to propose alternative latent variable models that, based on prior research or new theorizing, could be plausible representations of the relationships among

the constructs of interest than to present a single structural model that supposedly best represents the data. In other words, it is desirable that researchers adopt a model comparison approach to SEM (see MacKenzie, Lutz and Belch (1986), for a good example). Furthermore, researchers have to keep in mind that different specifications that can have very different substantive implications may fit the data equally or nearly equally well (MacCallum *et al.*, 1993).

Sample size. Researchers should make sure prior to data collection that the sample size will be adequate to avoid estimation problems and to get reliable fit statistics, parameter estimates, and estimates of standard errors. Although many kinds of factors can be expected to influence the required sample size, two kinds of heuristics for sample size determination have been proposed in the literature. Absolute guidelines are based on the notion that the sample size should be greater than a certain minimum number (e.g., there should be at least 200 observations). Relative guidelines specify that the number of observations per parameter estimated should exceed a certain minimum (e.g., ratios of 5 : 1 to as high as 20 : 1 have been mentioned). If sufficient prior knowledge is available, sample size determination can be based on desired levels of power (MacCallum, Browne, and Sugawara, 1996; *see also* STATISTICAL APPROACHES TO DETERMINING SAMPLE SIZES).

PRELIMINARY DATA ANALYSIS

One common mistake in applications of SEM seems to be that researchers fail to carefully examine their raw data before calculating the sample covariance matrix on which subsequent analyses are usually based. Space constraints prohibit a detailed discussion of the issues involved (Hair *et al.*, 2006), but researchers should ensure that the data have been coded appropriately, that missing values are dealt with using modern methods such as full information maximum likelihood or Bayesian multiple imputation, that outliers do not distort the sample covariances, and that the necessary distributional assumptions (e.g., multivariate normality) are adequately satisfied.

For the purpose of illustration, we use a dataset collected from 262 female staff members

at two American universities to study the model shown in Figure 2 (see Bagozzi, Baumgartner, and Yi, 1992, for additional information). Respondents completed a questionnaire measuring beliefs, attitudes, and intentions about using coupons for grocery shopping during the upcoming week (on the basis of 7-point scales, except for the second intention item, which was measured on a 11-point scale but linearly transformed to a range of 1–7), and one week later indicated how many coupons from 6 different sources in 21 product categories (plus an “other” category) they had used during the previous week. For simplicity, respondents with missing values were eliminated, leaving an effective sample size of 250, which, combined with a ratio of data points per parameter estimated of about 7, seemed adequate. Not surprisingly, coupon usage was strongly skewed to the right, so a square root transformation was used to normalize the data. Although the data are not multivariate normal (the data are discrete, the univariate skewnesses ranged from -1.35 to 0.83 , the univariate kurtoses from -1.43 to 1.91 , the relative multivariate kurtosis was 1.17 , and tests of univariate and multivariate normality suggested rejection of normality), it appears that the assumption is not too seriously violated. Robustness checks are reported later.

MODEL ESTIMATION

The goal of estimation is to find values for the five types of unknown parameters, based on the observed covariance matrix, such that the covariance matrix implied by the estimated model parameters is as close as possible to the sample covariance matrix. Model estimation also yields various goodness-of-fit statistics and standard errors for all parameters. A variety of estimation procedures have been proposed, but by far the most frequently used method is maximum likelihood assuming that the data have a multivariate normal distribution. Simulations show that the estimates tend to be robust to violations of normality, but the chi-square test of overall model fit and the estimates of the standard errors may not be. Estimation procedures that do not require multivariate normality are available, but adjustments to the normal-theory-based methods, which are easy to use, seem to work

well in practice (see Bentler and Dudgeon 1996, for more details).

Potential estimation problems are nonconvergence (a solution cannot be found within a given number of iterations or within a given time limit) and improper solutions (the values of sample estimates are not possible in the population, such as negative variance estimates). Common causes are poorly specified models, small sample sizes, and few indicators per factor.

There were no estimation problems with the present data set and LISREL 8.80 converged to a proper solution in less than one second (using a normal-theory-based fitting function). Ideally, more than two indicators should be available for all of the constructs, but this was not possible in the present case. Fortunately, the small number of indicators did not result in estimation problems.

OVERALL MODEL EVALUATION

Before the estimated model is interpreted in detail, researchers should ascertain that the specification is reasonably consistent with the data. If there are serious misspecifications and they are not attended to, the conclusions derived from the model can be seriously misleading. Of course, not all model misspecifications can be detected based on global goodness-of-fit indices, because alternative specifications that may have very different substantive interpretations can be equally consistent with the data (MacCallum *et al.*, 1993). However, if the fit of the model is found to be deficient, it has to be dealt with.

Global fit assessment is based on a summary measure of the discrepancy between the sample and model-implied covariance matrices. Theoretically, the fit of the model can be assessed using a statistic T which, under appropriate assumptions, has a central chi-square distribution under the null hypothesis that the specified model fits perfectly in the population. Depending on the particular assumptions made, there are different T statistics, but ideally they will lead to similar results. On the basis of the likelihood ratio criterion, one compares the likelihood of the hypothesized model to the likelihood of a model with perfect fit (the saturated model) and hopes that T will not be significantly greater than the

number of overidentifying restrictions (i.e., the degrees of freedom of the model).

Unfortunately, there are practical problems with the chi-square test of overall model fit. First, there is evidence that the test is not robust to violations of assumptions such as multivariate normality, although promising corrections to the traditional chi-square test, such as the Satorra-Bentler scaled (robust) test statistic, have been proposed in the literature. Second, the test is based on the accept-support logic, meaning that failure to reject the null hypothesis provides support for the researcher's model. On the one hand, this implies that a model is more likely to be supported when sample size and power are low, even though the chi-square test is only asymptotically valid. On the other hand, since most models are unlikely to be literally true in the population, larger sample sizes will ultimately lead to the rejection of a model even when the misspecification is relatively minor.

Because of these problems, many alternative (mostly descriptive) fit indices have been suggested. They can be classified on the basis of (i) whether they are goodness- or badness-of-fit indices (depending on whether an increase or decrease in the index signals a better fit), (ii) whether they adjudge fit in an absolute or relative sense (stand-alone vs. incremental fit indices, where the model of complete independence of all observed variables is generally used as the baseline model for the incremental indices), (iii) whether they are normed, approximately normed, or nonnormed (i.e., always or usually constrained to fall within a 0–1 interval in sample data, or unconstrained), and (iv) whether or not the fit index imposes a penalty for fitting additional parameters (correction for model parsimony or not). A detailed discussion is beyond the scope of this article. Some researchers question the value of even those indices which have traditionally been recommended in the literature (including the cutoff values associated with their use; see the recent exchange in the May 2007 issue of *Personality and Individual Differences*), but there is some consensus that a few indices based on different conceptual rationales should be used to assess overall model fit, and we briefly mention some of the more promising indices.

An intuitively appealing index is the standardized root mean square residual (SRMR), which summarizes the average size of the standardized residuals. It is a stand-alone badness-of-fit index, normed to fall between 0 and 1, and does not take into account model parsimony. Values up to 0.05 or maybe 0.10 are often considered to reflect satisfactory fit.

Another index is the root mean square error of approximation (RMSEA), which estimates how well the fitted model approximates the population covariance matrix per degree of freedom, using the noncentrality parameter to index error of approximation. It is computed as $\sqrt{(T - df)/((N - 1)df)}$, where T is the test statistic, df the degrees of freedom of the model, and N the sample size. A confidence interval for RMSEA is available, which provides information about the precision of the point estimate. RMSEA is a nonnormed, stand-alone badness-of-fit index which imposes a penalty for fitting additional parameters. Models with RMSEA values below 0.05 are assumed to have close fit, and values up to 0.08 or maybe 0.10 are considered acceptable.

The comparative fit index (CFI) is a normed, incremental goodness-of-fit index without a correction for model parsimony. It is also based on the idea of noncentrality and can be computed as $\left[1 - \frac{\max[(T_t - df_t), 0]}{\max[(T_b - df_b), (T_t - df_t), 0]}\right]$, where the subscripts refer to the target and baseline models, respectively. CFI should be at least 0.9 and maybe 0.95 or higher for a well-fitting model.

Finally, the nonnormed fit index (NNFI, the extension of the original Tucker-Lewis index in exploratory factor analysis to SEM) is an approximately normed incremental goodness-of-fit index which penalizes models containing more parameters. It is given by $\left[1 - \frac{(T_t - df_t)/((N - 1)df_t)}{(T_b - df_b)/((N - 1)df_b)}\right]$; the recommended levels are the same as for CFI.

A special class of fit indices are those based on information theory, such as the Akaike information criterion (AIC). They can be used to compare (even non-nested) models and take into account model parsimony. The model with the smallest value of the fit index (which with some definitions may be negative) is selected.

One common problem often observed in the application of many of these fit indices is that, after having to conclude that the specified model does not fit based on the chi-square test, researchers marshal evidence based on some alternative fit indices that the model is a good enough approximation. The goal seems to be to justify the initially proposed structure rather than to learn something new from the data. Furthermore, it is often unclear how much the original model was modified to bring the implied covariance matrix into reasonable congruence with the sample covariance matrix, in which case the overall model evaluation may not be trustworthy because of the dangers of capitalization on chance.

The fit statistics for the illustrative model are as follows. The T statistic based on normal-theory weighted least squares (the minimum of the normal-theory fitting function) was 92.60 (93.63) at 70 degrees of freedom, yielding a p -value of 0.04 (0.03). Thus, the fit based on the conventional chi-square test is borderline at an α -level of 0.05. When the normal-theory-based T was corrected for nonnormality using the Satorra-Bentler scaled test statistic, the resulting value was 83.57 ($p = 0.13$). The SRMR was 0.05, RMSEA 0.036 (with a confidence interval ranging from 0.0096 to 0.054), and both the CFI and NNFI were 0.99. All these indices suggest a very good fit of the model. This is somewhat unusual, but there are several reasons for this result. The model underlying Figure 1 is well established, the assumed belief structure is based on prior research, and the measurement of the remaining constructs is standard. Even when the model seems to fit well, it is advisable to inspect the results in greater detail to evaluate whether modifications are warranted, as described next.

MODEL MODIFICATION

Model modifications are usually motivated by mediocre overall fits of the initially specified model. Two primary tools are used for this purpose: modification indices (Lagrange multiplier tests) and residuals (the differences between the sample and implied covariance matrices). A modification index is reported for each fixed or constrained parameter and

it estimates the predicted decrease in the T statistic when a fixed parameter is freely estimated or an equality constraint is relaxed. Associated with each modification index is an expected parameter change (in original and various standardized scale units), which shows the predicted value of the freely estimated parameter. Assuming a chi-square distribution for T , a modification index exceeding 3.84 suggests a significant improvement of the model and a significant parameter estimate when the parameter in question is freely estimated (at an α -level of 0.05).

Residuals show the elements in the observed covariance matrix that are over- or underfitted, and this may also alert the researcher to components of the model that require attention. The raw residuals depend on the scale in which the variables are measured and sampling fluctuations, apart from possible model misspecification, but dividing each residual by the square root of the estimated asymptotic variance corrects for these confounds. These so-called “standardized” residuals (not to be confused with the standardized residuals on which SRMR is based) can be interpreted as z -values and indicate which residuals are larger than expected.

Although modification indices and residuals can be very useful, there are two potential dangers. First, if model modifications are primarily driven by the goal to improve the fit of the model (i.e., additional parameters are added based on the size of the associated modification indices), models that are hard to interpret substantively or theoretically may result. Furthermore, research has shown that data-based model modifications are not always able to recover the “true” underlying structure, and often the values of different modification indices are of similar magnitude, making it difficult to decide which parameter to free. It is therefore crucial that data-based model modifications be tempered by knowledge of the substantive area and theoretical considerations. Second, data-based model modifications may overemphasize idiosyncrasies of the particular data set and therefore might not hold up in future studies (the problem of capitalization on chance). Ideally, data-based model modifications should be reevaluated via more confirmatory follow-up research, or a cross-validation strategy

should be used in which the full data set is split into calibration and validation samples and the generalizability of modifications introduced in the former is examined in the latter.

Some authors (Anderson and Gerbing, 1988) believe that structural equation models should be evaluated in a two-step process (as many as four steps have been proposed), where in the first step no restrictions are imposed on the latent variable model (i.e., all covariances among the latent variables of substantive interest are freely estimated) and attention is focused on assessing the adequacy of the measurement model (e.g., whether indicators load on the "right" constructs, nontarget loadings are small and nonsignificant, the items individually and as sets are sufficiently reliable, and the constructs are discriminant). In the second step, the more constrained structural specification of interest is imposed on the latent variable model and the target model is compared to alternative specifications that are either more or less restrictive than the target model (the endpoints being the null and saturated latent variable models). If this detailed evaluation of the measurement and latent variable models reveals serious problems, appropriate model modifications to either model will be required (see Anderson and Gerbing (1988), for details).

For simplicity, we did not conduct separate analyses for the measurement and structural models in our illustrative example (the measurement model corresponding to Figure 2 had a T statistic based on normal-theory weighted least squares of 62.90 with 63 degrees of freedom). For the model in Figure 2 (which, as can be recalled, had a T statistic of 92.60 with 70 degrees of freedom), there were 11 significant modification indices (out of 131) and 9 significant standardized residuals (out of 105). The largest modification index (12.67) suggested a direct path from rewards to behavior, not mediated by attitudes and intentions. This was also supported by significant positive residuals from the two reward indicators to coupon usage (i.e., the initial model does not fully account for the observed covariance between the two reward indicators and coupon usage). When the path in question was freely estimated ($\gamma_{31} = 0.30$, z -value of 3.6), the T statistic based on normal-theory weighted least squares was 79.21 ($p = 0.19$). Most

parameter estimates and z -values in the revised model were very close to those in the initial solution, except that the magnitude of the coefficient from intentions to behavior decreased from 0.49 to 0.41. The variance accounted for in coupon usage increased from 0.34 to 0.37 in the revised model. There were still 10 significant modification indices and several significant negative residuals in the revised model, but the suggested changes were hard to interpret. Therefore, no additional model modifications were considered. Ideally, the added path from rewards to coupon usage should be validated in subsequent research, but since there is evidence from at least one prior study that rewards can influence behavior directly, there is precedence for this modification.

MODEL INTERPRETATION

A detailed evaluation of the measurement model should involve information about the estimated factor loadings and measurement error (unique) variances (including the variability of the estimates and T -values), evidence about measurement reliability (both for individual items and all indicators of a given construct combined), and some indication that the constructs in the model have discriminant validity (see also VALIDITY AND RELIABILITY). Individual-item reliability is simply the squared correlation between a construct ξ_j and an indicator x_i . It can be computed as $\rho_{ii} = \lambda_{ij}^2 \text{var}(\xi_j) / [\lambda_{ij}^2 \text{var}(\xi_j) + \theta_{ii}]$. It would be desirable if at least half of the variance of an observed variable were substantive variance rather than measurement error (unique variance), but this is often not the case. Two summary measures of reliability for all indicators of a construct are in common use. Composite reliability is the squared correlation between a construct and an unweighted sum of its indicators. It can be obtained as $\rho_c = (\sum \lambda_{ij})^2 \text{var}(\xi_j) / [(\sum \lambda_{ij})^2 \text{var}(\xi_j) + \sum \theta_{ii}]$. Average variance extracted (AVE) is the proportion of the total variance in all indicators of a construct accounted for by the construct, and it is calculated as the average of the individual-item reliabilities. Composite reliability is a generalization of coefficient alpha and therefore the same guidelines apply. Values below 0.6 indicate poor

reliability and above 0.8 are desirable. For AVE, values greater than 0.5 are deemed satisfactory.

Discriminant validity is commonly assessed in the following two ways. First, the correlation between two constructs should be significantly different from unity. This can be tested by constructing a confidence interval around the estimated correlation and checking whether the interval excludes 1. A more stringent test is based on AVE. Specifically, the AVE of the two constructs involved in a correlation should be greater than the squared correlation. This is based on the intuitive notion that a construct should have more in common with its own indicators than with other constructs.

In the illustrative example, all freely estimated loadings were highly significant, the individual-item reliabilities were mostly 0.5 or higher (the two exceptions were the second indicator of rewards with a reliability of 0.48 and the first indicator of encumbrances with a reliability of 0.24). In future research, the latter indicator should probably be modified. The composite reliabilities and AVEs were 0.76 and 0.61 for rewards; 0.88 and 0.78 for inconveniences; 0.70 and 0.44 for encumbrances; 0.88 and 0.65 for attitudes; and 0.92 and 0.85 for intentions. With the possible exception of encumbrances, all constructs seem to have been measured adequately. The largest (disattenuated) correlation is between attitudes and intentions (0.69) and discriminant validity is satisfied, based on both the criteria.

The latent variable model is what researchers will generally be most interested in. The sign, magnitude, and significance of the relationships

between the constructs test the hypotheses that the research was designed to investigate. In addition, researchers should report the variance accounted for in each of the endogenous variables so that readers can get an impression of the size of the effects (given that the estimated coefficients often do not have a natural interpretation).

Summary information about the latent variable model in the illustrative example is shown in Table 1. Reward beliefs have a positive influence on attitudes and inconvenience beliefs affect attitudes negatively. Encumbrance beliefs do not have a significant effect on attitudes. More favorable attitudes lead to higher intentions, and more positive intentions encourage greater coupon usage. In addition to the indirect effect of reward beliefs on behavior via attitudes and intentions (point estimate of 0.20, with a standard error of 0.04), there is also a direct effect (point estimate of 0.30, with a standard error of 0.08). Thus, the total effect of 0.50 is composed of a direct effect (61% of the total effect) and an indirect effect (39%). In other words, attitudes and intentions only partially mediate the effect of reward beliefs on coupon usage.

The final model was also analyzed using the Satorra-Bentler robust standard errors for the coefficients in the latent variable model and the results were almost identical. In addition, 100 bootstrap samples were drawn and analyzed and again the results were very similar and the substantive conclusions remained exactly the same.

It should be noted that any causal interpretations implied in the foregoing description are based on theoretical grounds and facilitated

Table 1 Summary information for the latent variable model.

| <i>Path</i> | <i>Parameter</i> | <i>Parameter Estimate (Standard Error)</i> | <i>Standardized Estimate</i> | <i>z-Value</i> |
|-----------------------------|------------------|--|----------------------------------|----------------|
| Rewards → attitudes | γ_{11} | 0.44 (0.08) | 0.47 | 5.59 |
| Inconveniences → attitudes | γ_{12} | -0.28 (0.06) | -0.38 | -4.85 |
| Encumbrances → attitudes | γ_{13} | -0.04 (0.10) | -0.03 | -0.41 |
| Rewards → coupon usage | γ_{31} | 0.30 (0.08) | 0.24 | 3.60 |
| Attitudes → intentions | β_{21} | 1.09 (0.11) | 0.69 | 9.88 |
| Intentions → coupon usage | β_{32} | 0.41 (0.05) | 0.48 | 7.96 |
| R ² (attitudes) | — | 0.42 | — | — |
| R ² (intentions) | — | 0.48 | — | — |
| R ² (behavior) | — | 0.37 | — | — |

to some extent by the design of the study (see also CAUSAL RESEARCH; CONCEPT OF CAUSALITY AND CONDITIONS FOR CAUSALITY). SEM per se does not warrant these conclusions. For example, coupon usage was measured one week *after* respondents indicated their beliefs, attitudes, and intentions. Although the self-report of coupon usage may have conceivably been influenced by people's memory of their previous responses, it is difficult to imagine that coupon usage (measured at a later point) could have influenced the other constructs in the model (measured at an earlier point). On the other hand, beliefs, attitudes, and intentions were all measured in the same questionnaire and the specification of the direction of the effects is based on one well-established theory (the theory of reasoned action), although one could probably adduce other theories to justify different patterns of effects.

OTHER USES OF SEM AND RECENT DEVELOPMENTS

In this final section we briefly mention some other uses of SEM and recent developments, which cannot be dealt with fully because of space constraints (see the edited book by Hancock and Mueller (2006), for review chapters on many of the topics in this section).

The models described so far are covariance structure models that ignore the means of the observed and latent variables. Furthermore, they are models for a single population. It is possible to extend the models to multiple known populations, in which case the means of the observed and latent variables can be incorporated as well. If latent means and path coefficients are to be compared across different populations, it is necessary to first establish measurement invariance. Depending on the type of comparison to be conducted, different degrees of measurement invariance are necessary (see Steenkamp and Baumgartner (1998), for details). For example, the data in the illustrative application were collected at two different universities and it might be of interest to establish whether the means of the different constructs or the strength of the relationships between constructs are the same for the two groups of respondents.

Traditional multigroup SEM assumes that each observation in the sample can be assigned to a population of interest a priori. Sometimes, however, the researcher may believe that the observations in a sample come from multiple populations, but the population membership of individual observations is not known. In this case, latent variable mixture modeling is applicable. The goal is to determine whether a mixture of multiple populations gave rise to the mean and covariance structure from which the sample under investigation was drawn, and to recover the separate model parameters for each of the multiple populations as well as estimate the mixing proportions. Such analyses may be useful for market segmentation and other investigations of unobserved heterogeneity (Jedidi, Jagpal, and DeSarbo, 1997; see also UNOBSERVED HETEROGENEITY).

Structural equation models usually involve only linear relationships (e.g., LISREL stands for linear structural relationships). However, sometimes it is of interest to investigate multiplicative or quadratic relationships of latent variables. For example, theories often specify moderator effects of one variable on the relationships between other variables. If such a theory is to be tested, an interaction model has to be specified. Although moderator hypotheses can be tested with multigroup structural equation models when the moderator is binary or the number of levels of the moderator is small, a different approach is needed when the moderator is continuous. Several approaches have been proposed to specify nonlinear effects in SEM. One key advantage of these models is that measurement error, which has even more damaging effects when interactions and quadratic effects are present, is taken into account explicitly. However, these models are also quite complex and they frequently require assumptions that might offset their perceived advantages.

The basic structural equation model assumes that the data are a simple random sample from a single underlying population. However, complex survey designs are sometimes used, where observations are sampled in multiple stages (e.g., first companies are sampled, and then salespeople within companies), the total population is stratified (e.g., by male and female

salespeople), and selection probabilities are unequal across strata (e.g., female salespeople have a higher probability of being included in the sample; *see also* SAMPLING TECHNIQUES; PROBABILITY SAMPLING). Multilevel SEM and sampling weights can be used to deal with these complications. For example, a researcher could specify a multilevel structural equation model and study (i) whether more motivated salespeople in a company are more likely to attain higher sales (within-company analysis) and (ii) whether companies whose salespeople are more motivated on average tend to have higher sales (between-company analysis).

Finally, SEM can be used for longitudinal analyses in which a researcher wants to study the trajectory of change in some variable(s) of interest and explain various aspects of the change trajectory (e.g., the linear rate of change) based on other variables, or use the change trajectory as an antecedent variable. In such an analysis, which is referred to as *latent curve* or *latent growth modeling*, the latent variables indicated by the repeated measurements (e.g., amount of cola consumed per year over a number of years) are individual-level curve parameters (e.g., intercepts and slopes if a linear trajectory is assumed, although other specifications are possible), which can subsequently serve as endogenous or exogenous factors in more detailed investigations of the change process.

CONCLUSION

SEM has become a valuable addition to the methodological toolbox of researchers in social sciences in general and marketing in particular. It combines a concern with measurement, which takes into account the inherent fallibility of single indicators of constructs, with the opportunity to model complex patterns of relationships among constructs. The scope of SEM is constantly being expanded and it can be expected that SEM will continue to flourish in empirical research in marketing.

univariate techniques

Rex Yuxing Du

Generally speaking, all statistical techniques can be characterized as either univariate or multivariate. Univariate techniques should be used for analyzing data when there is a single measurement (variable) concerning each element in the sample or when there are several measurements on each element but each measurement is analyzed independently or in isolation. On the other hand, multivariate techniques are applicable for data analyses when there are two or more measurements of each element and these measurements are examined *simultaneously*. The key distinction between univariate techniques and multivariate techniques lies in their different focuses. Univariate techniques are concerned with the levels (means) and distributions (variances) of each individual variable. For example, a sample of respondents may rate a brand at two different times. To determine whether there is a significant shift in the respondents' ratings over time, one can use a univariate technique, focused on examining the mean and variance of the differences in the respondents' ratings. By contrast, multivariate techniques are concerned with the degree of dependence or interdependence among two or more variables (correlations or covariances). To continue the previous example, suppose one has also collected data on the respondents' prior brand usage, ad exposure, category purchases, and so on, multivariate techniques can be used to examine how these variables covary along with brand ratings. This article focuses on a few univariate techniques most frequently encountered in marketing research. The analysis of frequencies, which does not involve statistical testing, is discussed in FREQUENCY DISTRIBUTION. For more details on various commonly used multivariate techniques, see CLUSTER ANALYSIS, CONJOINT ANALYSIS, EXPLORATORY FACTOR ANALYSIS, MODELS FOR CATEGORICAL DEPENDENT VARIABLES, MULTIDIMENSIONAL SCALING OF PREFERENCE DATA, DISCRIMINANT ANALYSIS FOR MARKETING RESEARCH APPLICATIONS, STRUCTURAL EQUATION MODELING,

ANALYSIS OF VARIANCE AND COVARIANCE, MULTIPLE REGRESSION.

Different univariate techniques can be classified on the basis of whether the focal variable is metric or nonmetric. A metric variable is measured on an interval or a ratio scale (also see PRIMARY SCALES OF MEASUREMENT). A satisfaction rating based on a five-point scale is an example of metric variable. Nonmetric variable is measured on a nominal or an ordinal scale. Survey questions with a yes or no response offer data in a nonmetric format.

For both nonmetric and metric variables, univariate techniques can be further classified based on whether a single sample or multiple samples are involved. Note that the number of samples is determined on the basis of how the data are treated for the purpose of analysis, as opposed to on the basis of how the data were gathered. For example, data for the general population may have been collected as a single sample, but if the analysis entails examining the potential differences between customers and noncustomers, two-sample univariate techniques should be applied.

Furthermore, when multiple samples are involved, the appropriateness of a univariate technique depends on whether the samples are independent or dependent (often also referred to as *paired*). Samples are deemed as independent if observations can be thought of as randomly drawn from different populations and there is no reason to believe any pair of observations (from different samples) are somehow related to each other. For example, to examine gender differences, data on males and females can be treated as from independent samples. On the other hand, two samples are deemed as dependent when each observation from one sample can somehow be paired with another observation from the other sample. For example, two observations are paired if they come from before-and-after samples of the same individual or right-side-and-left-side samples of the same individual. It is important to keep in mind that it is not the before-after that makes two observations paired, but the fact that they come from the same individual.

In sum, Figure 1 presents a classification of univariate techniques on the basis of (i) whether the focal variable is metric or nonmetric, (ii)

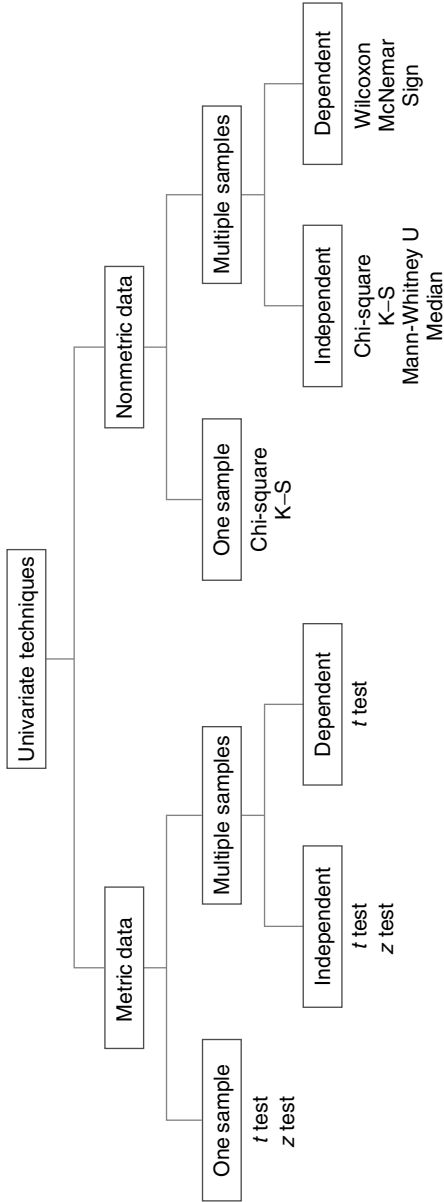

Figure 1 A classification of univariate techniques (adapted from Aaker, Kumar, and Day (2006). © John Wiley & Sons Inc., 2006).

whether there is one or multiple samples, and (iii) in the case of multiple samples, whether they are independent or dependent. The rest of the article focuses on three most frequently used univariate techniques: *t*-tests with metric data (interval and ratio), chi-square tests with nominal data, and Kolmogorov–Smirnov tests (K–S tests) with ordinal data. All three techniques can be applied to data from one or multiple samples. As for the other less frequently used and less versatile techniques, we provide a brief description on when they are appropriate and leave the details for more technical texts.

T-TESTS WITH METRIC DATA

One sample t-test. In marketing research, the researcher is often interested in comparing the mean of a single variable against a known or a given standard. For example, in doing research for a restaurant, the researcher might be interested in knowing whether patrons are satisfied with the restaurant's food. Respondents have provided their answers based on a seven-point interval scale where 1 = "Very Dissatisfied" and 7 = "Very Satisfied." Before attempting to address the "whether customers are satisfied" question, the researcher must perform a couple of tasks. First, he/she must develop the null and alternative hypotheses. For example, the researcher may be interested in determining whether the mean satisfaction level of the population exceeds 4, the neutral value on a seven-point scale. In that case, the null hypothesis may be stated as "the mean satisfaction level of the population is no greater than 4," and the alternative hypothesis as "the mean satisfaction level of the population is greater than 4." After developing the hypotheses, the researcher needs to select the level of significance for rejecting the null hypothesis (say, $\alpha = 0.05$, which means the chances of rejecting the null hypothesis when it is in fact true needs to be smaller than 5%).

After formulating the null and alternative hypotheses and selecting the significance level, the researcher can conduct a one-sample *t*-test, which is commonly used to provide inferences for making statements about the sample mean of a single metric variable. The *t*-test is based on the Student's *t* statistic. The *t* statistic assumes that the variable (*X*) is normally distributed across

the population, with the mean of the population (μ) known or assumed to be known, and the standard deviation of the population (σ) estimated from the sample. If these assumptions hold, then we know that the values of $t = (\bar{X} - \mu/s)$ would be *t* distributed¹ with $n - 1$ degrees of freedom, where \bar{X} is the sample mean, *s* the sample standard deviation, and *n* the sample size. The researcher can reject the null hypothesis and state that the mean satisfaction level of the population is above neutral if the value of the calculated *t* statistic (based on the sample) exceeds the critical *t* value (one-tailed in this case) for $n - 1$ degrees of freedom and a significance level of α . For more details on hypothesis testing related to differences, see HYPOTHESIS TESTING RELATED TO DIFFERENCES—PARAMETRIC TESTS.

Note that if the population variance (σ), like mean (μ), is assumed to be known, as opposed to estimated from the sample, a *z* test would be appropriate, where the value of $z = (\bar{X} - \mu/\sigma)$ would be distributed standard normal. However, because the *t* distribution approaches the standard normal distribution as the degrees of freedom increases, for large samples (say, 120 or more), the *t* test, and the *z* test are, for all practical purposes, equivalent.

Two independent samples t-test. Instead of simply making statements about a single population mean against a known or a given standard, which requires only one sample, marketing researchers are often interested in drawing conclusions about means from two different populations, which would require two independent samples; for example, users versus nonusers of a brand in terms of their category requirements, or high-income versus low-income consumers in terms of their time spent watching television. In such cases, *t*-test would again be appropriate.

After drawing independent samples of sizes n_1 and n_2 from two different populations and computing the means (\bar{X}_1 and \bar{X}_2) and standard deviations (s_1 and s_2), the researcher can compute the *t*-statistic as $t = (\bar{X}_1 - \bar{X}_2 - \Delta) / \sqrt{s_1^2/n_1 + s_2^2/n_2}$, where Δ is the hypothesized difference between the population means (0 if trying to determine whether the means are equal). The next step

4 univariate techniques

is to look up the critical t value in the t -table, with the number of degrees of freedom being the smaller of $n_1 - 1$ and $n_2 - 1$, and the significance level determined by the researcher. Whether to reject the null hypothesis depends on whether the computed t -statistic exceeds the critical value from the t -table.

If it is appropriate to assume that the two populations have equal (but unknown) variance (and therefore the same standard deviation), a pooled variance estimate can be computed from the two sample standard deviations as $s_p^2 = ((n_1 - 1)s_1^2 + (n_2 - 1)s_2^2) / (n_1 + n_2 - 2)$. The formula for computing the t -statistic using the pooled variance is $t = (\bar{X}_1 - \bar{X}_2 - \Delta) / \sqrt{s_p^2 (1/n_1 + 1/n_2)}$, and the corresponding number of degrees of freedom is $n_1 + n_2 - 2$.

Note that using pooled variance in a t -test is, in general, more likely to yield significant results than using separate variances. To determine whether the variances of the two populations are equal, an F -test may be performed, with the F -statistic computed as $F = (s_1^2/s_2^2)$. The critical F value for a given significance level can be found in an F -table, with two sets of degrees of freedom: $n_1 - 1$ based on the numerator and $n_2 - 1$ based on the denominator. If the computed F -statistic exceeds the critical F value, the null hypothesis of equal variance needs to be rejected and t -test based on separate variances should be used; otherwise, the t -test based on pooled variance can be used.

Two dependent samples t-test. In many marketing research applications, two related (or paired) observations are gathered from the same respondents. For example, a sample of respondents may indicate the relative importance of two attributes of a product, or rate two competing brands in one survey, or rate one brand at two different times (e.g., before and after an advertisement campaign). In these cases, it is the *difference* between the two related observations that is examined, which can be achieved by a paired-samples t -test. To compute the t -statistic for two dependent samples, the difference between the related observations, denoted by D , is formed and its mean (\bar{D}) and standard deviation (s_D) computed. The relevant formula is $t = (\bar{D} - \mu_D) / (s_D / \sqrt{n})$, with the degrees of freedom

being $n - 1$, where n is the number of pairs and μ_D the hypothesized mean of the differences.

CHI-SQUARE TESTS WITH NOMINAL DATA

Many variables in marketing research are measured on nominal scales. With these variables, the researcher is often interested in addressing questions such as “Do the numbers of responses that fall into different categories differ from what is expected?” or “Does the pattern of observed frequency counts based on one sample differ from those based on other samples drawn from different populations?” the *Chi-square test*, which is often referred to as the “*goodness-of-fit*” test, is a commonly used univariate technique to answer these questions. Below are two specific examples of research questions that could be examined by using chi-square tests.

- Do we have the same proportions of customers who visit our stores on an infrequent, moderately frequent, or very frequent basis?
- Does usage of mobile phone – never, low, moderate, and high – differ between the male population and the female population (two independent samples)?

The first question involves one sample and the null hypothesis is that one-third of the customer base falls into each of the three categories. The second question involves two independent samples and the null hypothesis is that the percentages of male mobile phone users falling into each of the four categories follow the same pattern as those of female users. In both cases, the general formula for calculating the *chi-square statistic* is $\chi^2 = \sum_{i=1}^K ((O_i - E_i)^2 / E_i)$, where K = number of mutually exclusive subgroups of respondents (differing in terms of either the categories of their responses or the populations to which they belong), O_i = number of respondents in subgroup i , and E_i = number of respondents expected in subgroup i if the null hypothesis is true. Under the null hypothesis, χ^2 follows the chi-square distribution, which is completely determined by its degrees of freedom, with the mean being

equal to the number of degrees of freedom and the variance equal to two times of the mean. When the degrees of freedom is large, the chi-square distribution is approximately normally distributed.

In the case of one sample, $E_i = p_i \times n$, with n = the total number of respondents and p_i = percentage of respondents falling into category i according to the null hypothesis. The degrees of freedom for one-sample chi-square test is $K - 1$. In the case of two independent samples, for subgroup i that belongs to sample s and response category r $E_i = (n_s n_c / n)$, where n_s = total number of respondents from sample s , n_c = total number of respondents falling into category c , and n = total number of respondents. The degrees of freedom for two-sample chi-square test is $(2 - 1) \times (C - 1) = C - 1$, with C being the total number of response categories.

KOLMOGOROV-SMIRNOV (K-S) TESTS WITH ORDINAL DATA

In many marketing research applications, the variable of interest is measured on an ordinal scale (e.g., never, infrequent, moderately frequent, or very frequent), where the spacing between adjacent scale points cannot be assumed to be the same. For convenience, such variables can be treated as if they were nominal, which, however, would be inefficient use of data because the scale points do follow a rank order. To fully utilize such information, K-S tests are often preferred. The K-S test compares the observed cumulative proportion with an alternative distribution. In the case of data from one sample, the alternative distribution is specified according to the null hypothesis. In the case of data from two independent samples, the alternative distribution is given by data from the other sample.

The K-S test is based on the maximum value of the absolute difference between O_i (the observed sample cumulative proportion through the i th ranked category) and A_i (the corresponding value given by the null hypothesis). The test statistic is $K = \text{Max } |A_i - O_i|$. Whether to reject the null hypothesis depends on the value of K ; the larger the K is, the more confidence one should have in rejecting

the null hypothesis. For significance level of 0.05, the critical value of K for large samples (over 35) is given by $1.36/\sqrt{n}$ (Kanji, 1999).

Note that the K-S test examines whether two distributions are the same, taking into account any differences between the two distributions, including the median, dispersion, and skewness. If the objective is to determine whether two independent samples are drawn from populations with the same median, *two-sample median test* would be more appropriate. If the objective is to determine whether there is a significant difference in the location (or central tendency) of two independent populations, the *Mann-Whitney U test* can be used, which corresponds to the two independent samples t -test for metric data with a pooled variance estimate.

Wilcoxon matched-pairs signed-ranks test (or simply *Wilcoxon test*) is an important test for examining differences in the central tendency of two samples with paired observations, which takes into account the magnitude of the differences measured on an ordinal scale. It first computes the differences between the pairs of observations and ranks the absolute differences. The next step is to sum the positive and negative ranks. The test statistic, z , is computed from the positive and negative rank sums. Under the null hypothesis of no difference, z is distributed standard normal with mean zero and standard deviation one for large samples. This test corresponds to the paired samples t -test discussed earlier for metric data (Malhotra, 2006, p. 488).

Another paired samples test for data collected by ordinal scales is the *sign test*. This test is not as powerful as the Wilcoxon test as it only compares the signs of the differences between pairs of variables without taking into account the magnitude of the differences. In the special case of a binary variable where the researcher wishes to test differences in proportions, the *McNemar test* can be used. Alternatively, the chi-square test can also be used for binary variables. For more on nonparametric tests, see NONPARAMETRIC TEST and standard statistical literature such as Higgins (2002) and Pett (1997).

ENDNOTES

¹The t distribution is similar to the standard normal distribution in appearance, both being bell-shaped and symmetric. Relative to the standard normal distribution, however, the t distribution has less area in the center and more in the tails (i.e., more variance), which is, intuitively, owing to the fact that population standard deviation σ is unknown and is estimated by the sample standard deviation s , which itself varies from sample to sample. As a result, one must go a larger number of standard deviations from zero to encompass a certain percentage of values from the t distribution than is the case with the standard normal distribution.

common methods bias

Wagner A. Kamakura

Assume a market researcher is interested in studying the relationship between customer satisfaction and customer loyalty. On the basis of theoretical considerations, one would expect that customer satisfaction measures would be correlated with measures of loyalty. However, if the measures of customer satisfaction and the measures of loyalty share common methods, those methods may produce a systematic effect on the observed correlation between the measures. In other words, subjects answering questions about satisfaction and loyalty within the same survey would be likely to correlate their answers to the loyalty questions highly with their answers to the customer satisfaction questions, simply to avoid cognitive dissonance. Therefore, the survey does not gather the “true” satisfaction and loyalty scores from the subjects because of common methods bias, which is likely to produce a spurious correlation between the two scores measuring customer satisfaction and loyalty.

Method biases are a problem because they are one of the main sources of measurement error. A measurement error threatens the validity of conclusions drawn from observed associations among measures and is known to have both a random and a systematic component. Although, both types of measurement errors are problematic, systematic measurement error is more critical because it produces spurious correlations that are due to the measurement instruments, rather than to the true association among the constructs being measured.

The influence of common methods variance has become a major concern in survey-based research (Podsakoff *et al.*, 2003), particularly for research involving self-reported measures (Spector, 2006). Much of the evidence of the extent to which method variance is present in behavioral research comes from meta-analyses of multitrait-multimethod studies (Campbell and Fiske, 1959; Cote and Buckley, 1987; Williams, Cote, and Buckley, 1989; Doty and Glick, 1998), which found that approximately one-quarter of the variance in survey-based research might be due to systematic sources of measurement error like common method biases (Cote and

Buckley, 1987). Common methods variance owing to systematic measurement error can cause observed correlations among variables to differ from their “true” population values (Doty and Glick, 1998), a manifestation of common methods bias. Common methods variance is not the same as common methods bias (Spector, 2006); whereas the former implies that variance in observed scores is partially attributable to a methods effect, common methods bias refers to the degree to which correlations are altered (usually inflated) owing to a methods effect.

Podsakoff *et al.* (2003) summarized the literature on common methods variance, identifying four main sources for this major threat to research validity as follows:

- common rater (e.g., SOCIAL DESIRABILITY BIAS, leniency)
- item characteristic effects (e.g., item ambiguity; *see* ITEMIZED RATING SCALES (LIKERT, SEMANTIC DIFFERENTIAL, AND STAPEL); PRIMARY SCALES OF MEASUREMENT)
- item context effects (e.g., priming effects, grouping of items)
- measurement context effects (e.g., simultaneous measurement of predictor and criterion variables).

Common methods bias is typically assessed and controlled for via CONFIRMATORY FACTOR ANALYSIS. One of the available approaches (see Podsakoff *et al.*, 2003 for a detailed discussion) is to specify each item in the measurement scale not only as an indicator of its substantive construct but also of a latent method factor, thereby controlling for common methods variance through the latent methods factor. Another popular approach is to use confirmatory factor analysis to directly model Campbell and Fiske’s (1959) multitrait-multimethod matrix, specifying both latent trait and latent method factors (Doty and Glick, 1998).

criteria for evaluating secondary data

Frank J. Mulhern

Secondary data are market research data collected for a purpose other than the one on hand. The data have the advantage of being much less expensive and more quickly available than primary data. However, because secondary data were collected for a different purpose, one must carefully evaluate their appropriateness for a given market research situation. Secondary data should be evaluated with the following criteria in mind:

- *Accuracy:* The accuracy of secondary data refers to the intrinsic quality of the data. That is, the extent to which one can assume the reported data are correct. Problems with accuracy can result from several factors including nonresponse in surveys, missing values in a database, data entry mistakes, and tabulation or reporting errors. Concern should also be placed on the reliability and validity of the data (*see* RESEARCH RELIABILITY AND VALIDITY).
 - *Relevance:* The relevance of secondary data represents their usefulness for the purpose at hand. Even if data are highly accurate, they may be of little value if they lack relevance for the given research situation. Relevance stems from several aspects including the following:
 - *Method of data collection:* The data collection method has enormous effect on many aspects of the data and their relevance for a given purpose. In particular, one should determine if the data came from self-reports, as in the case of survey data (*see* SURVEY RESEARCH) versus behavioral measures such as purchase histories (*see* INTERNAL DATABASES FOR MARKETING RESEARCH).
 - *Units of measure:* Using secondary data precludes the ability to specify the units of measure. For example, a researcher wanting to analyze market share of dollar sales may be unable to do so with data on market share of unit volume.
 - *Level of aggregation:* Users of secondary data must work with levels of aggregation that exist in the data. For example,
- brand sales for a liquid product might be expressed in terms of the number of packages of all sizes, the equivalence of one size such as quart bottles, or total volume. Aggregation of consumers is also an issue. Data can be reported at different levels of aggregation such as individual consumers, households, or various levels of geographic market areas.
- *Time increments:* Many forms of data involve time increments such as days, weeks, months, or quarters. While small time increments can be aggregated into larger ones (e.g., daily data can be combined into weekly), larger time units cannot be disaggregated into smaller ones.
 - *Data format:* Working with secondary data can be difficult because data often arrive in undesirable formats that require substantial preparation before analysis can take place. Some datasets come in formats that can only be accessed by certain software.
- *Data documentation:* Secondary data should be accompanied by information on the variable definition, method of data collection, and the like. Researchers reporting on analyses of secondary data will be expected to explain the definition and interpretation of all the variables in the dataset.
 - *Currency and timeliness:* Currency refers to how recent a time period the data represent. Recently collected data are generally more desirable. Timeliness refers to how quickly the data can be obtained and when future updates may be available. A common advantage of secondary data is that they can be obtained much more quickly than primary data.
 - *Cost:* Secondary data can be expensive to purchase. In addition to the upfront costs of acquisition, one should consider additional costs for data preparation, storage, and so on.
 - *Usage terms:* Many secondary data sources place restrictions on who may use the data, what the data may be used for, and the length of time a user may access them. Users of secondary data should be aware of such restrictions.

2 criteria for evaluating secondary data

By evaluating prospective sources of secondary data with these criteria, market researchers can take advantage of the convenience and cost-effectiveness of secondary data (Kiecolt and Nathan, 1985).

internal databases for marketing research

Frank J. Mulhern

Direct marketing and database marketing are two highly related practices that combine the use of customer-level information with marketing communications through direct media. Direct marketing refers to any marketing communication that uses a direct media technology to communicate to individuals, in contrast to mass media, which communicates to large audiences. Direct media include mail, telephone (including mobile), and print catalogs as well as interactive forms of media such as e-mail and online advertising. Database marketing refers to the practice of gathering, compiling, and analyzing information on individual customer purchase behavior and using that information to select target consumers and execute communications. Direct marketing is characterized by the ability to address individual consumers by name, target consumers based on knowledge of past purchases, communicate with direct response mechanisms that facilitate purchasing, and measure consumer response with precision.

Direct marketing is most effective when it is based on detailed information on consumer behavior stored in customer databases. Customer databases are constructed with information on purchase behavior obtained from a variety of sources including retail stores, response to previous direct marketing, online shopping, and media subscriptions. Databases also may contain descriptive information on individuals obtained from public sources such as home purchases and car registrations.

In contrast to survey research, which is self-reported, customer databases represent a form of unobtrusive data that reflects actual behavior. Marketers analyze the information in databases to identify target customers and formulate communications strategies. Customers are often targeted on the basis of their estimated value to a firm. Customer value represents the past or future value of a customer on the basis of the revenue a customer provides through purchases and the costs incurred in serving that customer. A common approach to measuring customer value is to compute three elements: *recency* – how much time has passed since a

previous purchase, *frequency* – how frequently a person has made a purchase, and *monetary value* – the total dollar value of past purchases. Database marketers use scoring models that combine such information into a single score to prioritize who should be targeted. Direct marketing communications are then used to solicit responses from the consumers with the highest scores.

A second area of database analysis is customer segmentation. A major advantage of customer databases is they allow for precise specification of market segments compared to the more limited information used in segmentation with demographic or survey data (see SURVEY RESEARCH). Database marketing allows for precise segmentation based on past purchases, price and promotion responsiveness, and projected lifetime value. While the same multivariate statistical methods used for survey research can be used for database segmentation, additional classes of analysis, known as *data mining*, can also be used. Data mining consists of methods that systematically analyze large databases to identify patterns or provide summary information.

A third area of database analysis is customer response analysis. These are similar to market response models that assess the impact of marketing mix variables on buying behavior. However customer response analysis is more precise because it reveals exactly which customers respond to which marketing communications.

As media becomes more digital, the direct, and database marketing approaches are becoming more central to marketing as a whole. Mass marketing approaches pioneered in the print and broadcast era are giving way to more precise and efficient marketing communications driven by information in customer databases and the capabilities of direct marketing and database marketing. As television becomes digital and merges with the Internet, the direct and database marketing model will dominate advertising as real-time information on audience television viewing is captured in databases and used to serve targeted ads. In many ways, direct marketing and database marketing represent a revolution in marketing practices that feature a high level of information and the ability to communicate with individual consumers.

2 internal databases for marketing research

A few key limitations challenge the practice of direct marketing and database marketing. Direct media can be very bothersome to consumers as unwanted telephone calls, mail, e-mail, and online ads intrude into people's lives. Through technologies and other means, consumers attempt to avoid the intrusiveness of direct marketing. Privacy concerns exist because many consumers oppose the collection and use of extensive information on their purchase behavior. Many countries have extensive regulation of what marketers can or cannot do with information in customer databases. A common practice, particularly for online and mobile communications, is to limit direct marketing to consumers who opt-in to solicitations from specific companies. Finally, the development of new communications technologies forces

direct marketers to continually modify practices to accommodate new business models and communication practices. Direct marketers are adjusting their approach to accommodate a world where consumers, not marketers, have control over media experiences.

ethnographic research

Linda L. Price

Ethnography is a research practice that places researchers in the midst of what they study. That is, it takes place “in the field” rather than in experimental setups or highly structured interview situations (see FIELD WORK/DATA COLLECTION PROCESS). Ethnography involves participating overtly or covertly in people’s daily lives for an extended period of time, watching what happens, listening to what is said, asking questions, and gathering whatever data are available to inform the inquiry.

At its core, ethnography attempts to describe and interpret, cultural and social life (see SUBCULTURES). It has been defined as the science of cultural description. Terms such as “total immersion,” “thick description,” “deep hanging out,” and “subjective soaking” used to describe ethnography, convey that it is directed at obtaining and representing a deep understanding of the lived experience of people as it unfolds in a particular cultural context. Ethnography refers both to the fieldwork and the representations based on that fieldwork. Most ethnographic research is concerned with producing descriptions and explanations of particular phenomena or with developing theory rather than with testing a set of hypotheses. The ethnographer is interested in depth and understanding rather than breadth and prediction.

Ethnographers typically draw on a range of sources of data, but participant and nonparticipant observation, interviews, conversations, and informant diaries are among the most common types of data used (see OBSERVATION METHODS). Data collection is relatively unstructured. The research design is a continuous reflexive process that operates throughout each stage of a project. Ethnographers anticipate that the initial questions that motivated the research will be refined or even transformed over the course of the investigation. Categories used for interpreting what people say or do are not typically built into the data collection process, as would be the case with many other types of data collection such as observation schedules, experiments, or questionnaires, but are instead generated out of the process of

data analysis. The focus is generally small scale to facilitate in-depth study, but multisited and multivocal ethnographies are increasingly common especially for ethnographers doing commercial market research. Gaining access to the data can be particularly problematic in ethnography, because the researcher often operates in settings where the researcher has little power. New tools such as netnography, used in on-line social systems, and consumer-generated video diaries have expanded ethnographer access to naturally unfolding consumer and marketer actions and practices (see ONLINE CONSUMPTION).

Analysis of data is open-ended, flexible, and adaptive. No two ethnographies have ever been conducted in exactly the same way. Ethnographers attempt to understand the informants’ points of view (emic) and to portray broader cultural meanings (etic). Data analysis involves interpreting meanings, functions, and consequences of actions and practices of people and institutions. Systematic reading and viewing of collected data and field notes are used to ground tentative themes and hypotheses to the data and generate new ones. Researchers often undertake a process termed *open coding* (unrestricted line by line coding) to identify and extract themes and issues. Next, ethnographers begin to notice and create records of patterns in the conversations and activities of people depicted in field notes. Several commercial programs are available for qualitative data storage, handling and retrieval, but these programs do not analyze data in a way comparable to quantitative software. In reporting themes and patterns observed in the data, ethnographers may rely on inductive content analysis to suggest the magnitude or frequency of identified themes and patterns or alternatively compose an ethnographic narrative account connecting what people say and do with available theoretical interpretations (see CONTENT ANALYSIS). The latter approach is most common in consumer and marketing ethnographies. A number of different criteria might be used to evaluate the trustworthiness of the account including adequacy, resonance, integration, innovation, and usefulness.

Ethnography is perhaps the oldest methodology of social investigation. Over the past two decades marketing, and consumer theory

2 ethnographic research

and research have established ethnography as an important marketing research tool. Ethnography is useful for a wide range of problems including understanding disjunctures between what people say versus what people do, identifying taken for granted practices and linking them to shared cultural templates and meanings, and uncovering complex interplays of marketing phenomena and people in social systems. Ethnography, or quasi-ethnography, is now a standard offering in the world of commercial market research. The conduct of ethnography can seem deceptively simple, but it is a demanding activity, requiring diverse skills, including dealing with uncertainty and the ability to identify patterns in complex arrays of social meanings and behaviors, and link these patterns to existing social theories.

experimental design

Harmen Oppewal

Experiments focus heavily on *internal validity*, which concerns whether an observed relationship is a true causal relationship (see VALIDITY IN EXPERIMENTATION). The aim is to rule out any alternative explanation of the relationship observed in the experiment between the independent variables and the dependent variables (Shadish, Cook, and Campbell, 2002). Suppose we wish to test the effects of a loyalty card on customer spend. Existing company data may suggest that card owners spend more. However, card ownership may be higher among customers with higher income levels. Card ownership is therefore *confounded* with customer income in the company's data and income may well be the real cause for the observed higher spending by card owners.

To rule out such alternative explanations, or "third variables," experimental designs comprise two core features: control and randomization. *Control* means that the researcher actively manipulates the factors of interest while keeping other variables as much as possible constant. To study the effects of a loyalty card we need to keep the card conditions fixed over the study period and retail outlets. It is difficult to fully control all possible variables. This is why experiments are typically conducted in controlled environments. Test conditions are standardized to avoid that other factors can covary and influence the outcomes. Additional variables can be measured to serve as potential statistical controls in the analysis.

Randomization takes over where control cannot be achieved by other means. Test units are assigned to different conditions based on mere chance, for example, by using a probability generator. In our example, we would determine by random draw who receives the loyalty card and who does not. In that case, any observed difference in the outcome between the two conditions can only have been caused by the manipulation, or by the combined effect of all other possible variables on which the test units differed, including, for example, age and gender. Because units were randomly assigned, we can use statistical theory to derive the probability

of such differences appearing based on chance alone (see CAUSAL RESEARCH). If an observed outcome is too unlikely to be a mere chance effect, we conclude that the only other possible cause is the manipulated difference between the conditions.

The implementation of random assignment requires that the researcher sets the stage and "manipulates" the conditions according to the predetermined plan that includes a procedure for random assignment. This is not always feasible in practice. Applied research often uses existing groups or sites and typically these cannot easily be split and allocated to different conditions. Similarly, it may be difficult, or even unethical to create different conditions (see ETHICS IN MARKETING RESEARCH).

Finding the best ways of implementing manipulation and control is the subject of "experimental design." Although, the focus in experiments is on internal validity, which is best achieved under homogeneous and specific circumstances, there is always a trade-off with external validity. Especially in applied research, there is often a strong call for studying "real" situations, and for good reasons. The more similar the test situation to the target situation, the less burden there is for the researcher to show that the results will apply to the target situation. *Field experiments* are experiments that are conducted using real or realistic settings. Sometimes the situation allows maintaining proper levels of control and randomization without any artificiality to the setting. Such studies are however exceptions and depend a lot on the ingenuity of the researchers to find a suitable design.

Often researchers have to live with the design limitations that the study setting or budget imposes and random assignment of individual test units cannot be achieved. This is, for example, the case where existing groups or conditions are utilized, such as when different student classrooms are exposed to different advertisements and asked to rate an advertisement's appeal. When strict randomization cannot be applied, the research design becomes a "*quasi-experimental*" design (Cook and Campbell, 1979). Because no proper randomization can be applied, statistical theory cannot be used to automatically rule out "third

2 experimental design

variable” effects. As a consequence, there is greater burden on the researcher to argue explicitly and, where possible, demonstrate that no third variables have influenced the outcomes. (see VALIDITY IN EXPERIMENTATION).

purchase, scanner, and media panels

Frank J. Mulhern

Purchase, scanner, and media panels are collections of individuals or households who agree to provide detailed information on their behavior over a period of time. Participants in these panels provide marketers with detailed information on purchase behavior or media use. Panels are designed to represent the demographic and ethnic population of the nation, and range in size from a few thousand to tens of thousands of participants (Sudman and Wansink, 2002).

PURCHASE PANELS

In purchase panels, participants record information about what they buy. Typically, participants, upon returning from a shopping trip, enter their purchase information into either a diary or an online data collection system (see WEB SURVEYS). The largest provider of purchase panel information is the NPD Group (www.npd.com). NPD manages an array of panels in over 20 countries. Data from the panels are analyzed and reported by industry type, including automotive, health and beauty, consumer technology, groceries, and so on. Brand marketers obtain information from the panels on the demographic composition of their customers and where they make their purchases.

Purchase panels have the advantage of providing information on essentially everything a household purchases, unlike other data sources which tend to be limited to a few product categories, or a single retailer. Purchase panels allow for analysis and interpretation of what brands people purchase over time, which brands are purchased at which retailers, and how the composition of household spending varies over time.

The disadvantage of purchase panels is that they require the participants to enter information manually, either on paper or a computer. Participants may neglect to enter information for all their purchases for a variety of reasons including carelessness (see RESEARCH RELIABILITY AND VALIDITY) and concerns about privacy (see INTERNAL DATABASES FOR MARKETING RESEARCH).

SCANNER PANELS

Scanner panels are a special type of purchase panels, where participants are enrolled in a program that automatically captures data on their purchases at retail stores. Scanner panels overcome the limitation of requiring participants to input information manually. AC Nielsen operates a major scanner panel called *Homescan*, where consumers scan purchases when they return from shopping.

In some cases, the data collection of panel members takes place at stores. Scanner panels can be for a single product category or more broadly for all purchases. Store-based scanner panels capture participants' purchases across several retail chains. Scanner panels tend to be much smaller than purchase panels because the cost of collecting the data is higher since retailer point of sale systems must be integrated into a single process across stores. Scanner panel data is an excellent source of information about repeat buying, brand switching, price sensitivity, and promotion response with multiple regression models (see MULTIPLE REGRESSION).

MEDIA PANELS

Information on media consumption behavior is necessary for advertisers to successfully place ads where they will be seen by target audiences. That information comes from media panels that consist of households who agree to have their media use tracked by electronic devices. By far, the most important media panel is the Nielsen Television Index (NTI) operated by Nielsen Media Research (www.nielsenmedia.com). The NTI panel consists of 5000 households whose television viewing is captured by an electronic "peoplemeter" that tracks, when the television is on, what channels are watched and who in the household is watching. Data from the NTI measures the size of audiences for TV shows and advertisements and is used to establish prices for advertising placements. Radio consumption is measured by Arbitron (www.arbitron.com) through diary entries about which radio stations participants listen to and in what situations. Print media use is measured not with panels but with data on *circulation*, a measure of distribution, and *readership*, a survey-based (see SURVEY RESEARCH) measure

2 purchase, scanner, and media panels

of how people say they read newspapers and magazines.

With the growth of the Internet as a medium, services are providing measures of news, entertainment, and advertising consumption online. Nielsen Netratings (www.netratings.com) is one of a variety of services that track and report on Internet use. BIGresearch (www.bigresearch.com) conducts an extensive media panel with over 8000 participants. Participants enter information about media consumption through an online data collection system. BIGresearch provides detailed information on both traditional and online media use in their simultaneous media usage study.

While panels provide excellent information for marketers, they suffer from problems related

to sampling (*see* SAMPLING TECHNIQUES), participation, and attrition. While participants are recruited to represent the population at large, panels often have difficulty achieving proper representation. In such cases, the data is statistically adjusted to better represent the population. Attrition, panel members quitting participation, is particularly a problem because it distorts the representativeness of the panel data over time. Panel companies financially compensate participants to minimize attrition.

validity in experimentation

Harmen Oppewal

TYPES OF VALIDITY

Four types of validity are to be considered when evaluating whether research findings can be interpreted as a legitimate test of a hypothesized relationship between an independent and a dependent variable (Cook and Campbell, 1979). They are construct validity, statistical conclusion validity, external validity, and the one at which experiments excel: internal validity. Validity, in general, is discussed in RESEARCH RELIABILITY AND VALIDITY. This article focuses on validity in experimentation.

- **Construct validity** concerns whether the operations and variables in the experiment correctly represent the theoretical constructs as intended. This includes the research setting, the experimental manipulations, and the dependent variable (*see* RESEARCH RELIABILITY AND VALIDITY).
- **Statistical conclusion validity** concerns whether statistical assumptions and procedures are valid and are correctly applied in the analysis. This includes whether randomization has been properly implemented (*see* EXPERIMENTAL DESIGN).
- **External validity** concerns whether the observed relationships can be extrapolated, or generalized, to other samples of units (e.g., people), situations, or times. If a study is conducted in more realistic settings, then there is a smaller gap between the test situation and the setting that actually needs to be understood, making generalizability, which always remains a leap of faith, less of an issue (Shadish, Cook, and Campbell, 2002). An argument that is often used by experimenters is that if no relationship can be established under controlled circumstances there is no point looking at external validity. Once the relationship has been established, further testing is required to assess the “boundary conditions” beyond which the relationship does no longer apply (Calder, Phillips, and Tybout, (1981, 1982); Lynch, 1982).

- **Internal validity** is the extent to which alternative explanations for an observed relationship between variables can be ruled out. In other words, did the independent variable really cause the change in the dependent variable? Through the use of standardized, experimentally controlled conditions, and random assignment of participants to the conditions, experiments allow answering this question with maximum levels of confidence.

THREATS TO INTERNAL VALIDITY

Although, for any other type of research the internal validity of a relationship has to be explicitly considered and argued for, in properly conducted experiments internal validity is almost automatically guaranteed. Cook and Campbell (1979) identified several types of threats to internal validity.

- **Selection bias** is the most severe internal validity threat. It concerns any systematic difference between the experimental groups not accounted for through standardization or randomization. In experiments, selection is mostly an issue if it occurs in combination with one of the other threats; vice versa the threats below are only a real issue in the experiments if they affect different experimental groups in different ways.
- **History effects** can occur when experimental groups are exposed to different external events during the course of the experiment. The change in the dependent variable can therefore not be uniquely ascribed to the experimental procedure.
- **Maturation effects** are any changes within the experimental units, whether respondents, organizations or sites, that occur during the experiment, and that are not induced by the experimental manipulation. If such changes appear only in particular experimental groups, the experimental results cannot uniquely be attributed to the experimental treatment.
- **Testing effects** occur where exposure to the experimental measures (instead of exposure

2 validity in experimentation

to the treatment) results in a change in the experimental units. If respondents in an ad test, before seeing the ad, are asked about their brand perceptions, the mere exposure to these perception questions may result in improved brand recall. This improvement should not be attributed to the ad as it is an effect of having been asked questions about the brand.

- **Instrument variation effects** may occur when different measurement instruments are used for different experimental groups resulting in differences in the dependent variable, for example, if in one condition respondents answer a paper-and-pencil task while in another they answer an online task.
- **Statistical regression** occurs if participants are selected for different conditions on the basis of their performance on some test. Because of the measurement error in the pretest, there will be a natural tendency for participants with high scores to display somewhat lower scores if a similar test is conducted again, for example, after the experimental manipulation. The opposite will happen to participants with a low pretest score.
- **Experimental mortality** concerns whether respondents complete the experimental

tasks. If in a satisfaction study one condition takes longer to complete this may result in fewer people completing this condition. If these dropouts are the ones that are less satisfied with the product, the result will be that the remaining group achieves higher scores than they would have otherwise. Clearly, this is an artifact and not evidence that satisfaction has increased (*see* CUSTOMER-SATISFACTION RESEARCH).

web surveys

Tuo Wang

A web survey is a self-administered survey conducted on the Internet or through a website. Instead of sending a questionnaire to a respondent, the questionnaire is stored electronically on a web server. To complete the questionnaire, a respondent, usually clicks a link that leads to the web server. When the respondent finishes the survey, the survey data is sent to a server via the Internet. Researchers can retrieve the stored survey data from the server anytime via the Internet. Web surveys can be conducted either through invitation by the researcher (often delivered via e-mail) or by a “pop-up” window that appears when a potential respondent visits a certain website. The percentage of US households with Internet access has been increasing rapidly. Web surveys have become more attractive to marketing researchers owing to the increasing representativeness of web survey respondents. If the sample for a web survey is carefully selected and fits the target population, a web survey can provide both efficiency and quality. Web surveys enjoy unbeatable advantages over traditional (snail) mail surveys in terms of saving time (e.g., mailing and data entry) and money (e.g., costs associated with printing, mailing, and data entry). When interactive technologies are properly applied, a web survey can also enhance questionnaire flexibility and provide visual stimuli to the respondents. The limitations of the web survey are (i) the requirement of easy access to the Internet for respondents and potential sampling frame bias (when the Internet is not easily available to

certain segments of the target population); and (ii) the unknown quality of a web survey’s results when an interest group can potentially manipulate responses or when Internet security may be compromised. Another concern when using web surveys is the potentiality of low response rate when compared to a mail survey Cook, Heath, and Thompson, (2000). This may be a serious problem for some web surveys when the soliciting emails are classified as “spam” or “junk mail”. Nonresponse bias is a problem that web surveys need to overcome, either through “propensity scoring,” which gives more weight to underrepresented respondents, or through the use of a complementary data collection method, such as a traditional mail survey.

To conduct a web survey, researchers can either design the survey using web-based programming language (e.g., HTML) or using commercial software that enables them to create a web-based survey without programming skills (e.g., surveymonkey.com). In summary, web surveys are gaining popularity as the Internet becomes easily available to a larger population. Web surveys save time and money for the researcher. According to Research Industry Trend 2006, web-based surveys are now the most popular survey method with 36.8% of total usage.

comparative evaluation of survey methods

Tuo Wang

There are generally four criteria used to evaluate a survey method: speed of data collection, cost, data quality, and flexibility. The choice of an appropriate survey method thus depends on answers to the following questions: (i) How soon does the researcher need the information? (ii) How much can the researcher spend on data collection? (iii) What is the data quality desired by the researcher? (iv) How much flexibility is desired by the researcher?

HOW SOON DOES THE RESEARCHER NEED THE DATA?

When time is short, the researcher may have to compromise quality for speed. Time to complete a survey includes deployment time, respondent recruitment time, and response time. Response time is likely to be the most unpredictable when a survey is self-administered. All things considered, the choice of a survey method when speed is a priority can be evaluated as follows:

Fast methods.

1. *Mall-intercept interviews:* This also includes intercepting shoppers in other high-traffic locations. Owing to the high density of shoppers in these locations, as well as the high response rate for personal interviews, this method can potentially generate a high number of survey respondents in a short time period. When the demographic profile of the target population needed for the research is similar to a mall's shoppers, this approach can save both time and money for the researcher without significantly compromising data quality.
2. *Web surveys:* These can be very fast if respondents are provided with the right incentives to complete the survey. There is no delay between sending and receiving the data.
3. *Telephone interviews:* Without knowing the availability of a potential respondent (call blocking, bad timing, etc.), it may take additional time to recruit qualified respondents with the first filter question. Once a respondent is contacted and agrees to participate,

researchers can quickly get the response without further delay.

Slow methods.

1. *Personal interviews:* These require extra travel time for the interviewer.
2. *Mail surveys:* This is the slowest survey method, primarily owing to the long lead time for preparation and deployment, as well as potential response delays by subjects. A reminder or incentive needs to be provided to reduce response delay.

It is important to recognize that there are a large number of vendors that provide specialized services to collect data by using different survey methods. Major vendors of research services are listed in "The Green Book". The response time, or time to collect necessary data, can be reduced by hiring outside vendors. For example, the response time for an online survey may range from one day to two weeks. For a mail survey, it may take an average of one month to obtain data from those who are likely to respond. An outside vendor can easily reduce the response time by hiring an adequate number of interviewers to collect data through face-to-face interviews or telephone interviews. Vendors can collect data within weeks from these methods. Thus, response time of a survey method is dependent upon the budget available for collecting the data.

HOW MUCH CAN THE RESEARCHER SPEND ON DATA COLLECTION?

Generally speaking, the least expensive method per interview is the web survey (no interviewers cost, no mailing cost, and no data entry cost) McDaniel and Gates, 2007, p. 181. Mail surveys are traditionally economical choices in the absence of interviewers. Telephone interviews are also reasonable compared to personal interviews, but are losing ground to web surveys owing to the availability of Internet access in more households. The most expensive is personal interviews, which involve both travel cost and compensation for quality interviewers.

When evaluating costs of using different methods, one needs to separate and consider the fixed and the variable cost per survey. The major fixed cost involves training/hiring interviewers, buying/renting software to design

2 comparative evaluation of survey methods

the survey, and hiring skilled/unskilled labor. The variable costs involve the cost of buying mailing or e-mail addresses, postal charges, and telephone numbers (Groves, 2004). In general, except for the face-to-face interview, the variable cost per completed survey does not exceed a few dollars per survey, whereas the telephone and face-to-face interview result in high fixed costs owing to the need for skilled personnel to conduct the interviews.

WHAT IS THE DESIRED DATA QUALITY?

Any survey method is prone to error. The researcher tries to minimize the systematic error (or bias). If a survey is conducted by an interviewer, interviewer bias is likely to be present. If a survey is self-administrated, nonresponse bias may be serious and needs to be addressed (Groves, 2004). A general rule of thumb is (i) a more expensive survey method generates better data (better interviewers, better sampling, etc.); (ii) a survey that is more time consuming generates better data (respondents have more time to think about the questions or to interact with interviewers).

HOW MUCH FLEXIBILITY IS NEEDED BY THE RESEARCHER?

Again, personal interviews are the choice when maximum flexibility is required (Aaker, Kumar,

and Day 2001, p. 237). Personal attention from a good interviewer ensures flexibility even when the researcher is not aware of, or cannot anticipate, the potential problems before the interview/survey is conducted. When differences among respondents can be classified before the survey is administered, web surveys are a good choice, having the ability to deliver a high level of personalization (the survey questions can be customized easily on the basis of respondents' answers to previous questions). Mail surveys or web surveys are better choices than telephone interviews when pictures are required. Mall-intercept interviews are ideal when physical products need to be demonstrated or sampled.

Please see SURVEY RESEARCH for further details regarding different survey methods.

comparative scaling technique

Vanitha Swaminathan

Scaling is the process by which questions are used to assign numerical values to measure subjective properties of an object. In marketing, scales are used to quantify a variety of aspects, including brand attitudes and brand preferences, liking for various ads, and so on. Sometimes, scales can be used to measure the extent to which two or more entities can be compared or evaluated, for example, advertisements or brands.

There are four types of comparative scales: (i) paired comparison; (ii) rank order; (iii) constant sum; and (iv) *Q-sort*.

- 1. *Paired Comparison*: A paired comparison is a specific type of comparative scaling technique. In a paired comparison, two versions of a new product may be tested against each other. Respondents can be surveyed following a product use involving the two versions of the new product, as described below.

Which of these two brands – Breyer’s or Ben & Jerry’s do you think is better?

☐ Breyer’s ☐ Ben & Jerry’s

- 2. *Rank order*: In this type of comparative scaling method, respondents are asked to rank order various options as shown below. Rank each of the following brand names from most preferred to least preferred (1 = most preferred and 5 = least preferred):

| | Ranking |
|---------------|---------|
| Breyer’s | _____ |
| Ben & Jerry’s | _____ |
| Häagen-Dazs | _____ |
| Klondike | _____ |
| Turkey Hill | _____ |

- 3. *Constant sum*: In the constant sum scale, respondents are asked to assign points to each of the options with more points assigned to the more preferred option.

Please assign 100 points across each of the following brands based on your relative preference for each of these brands (please note that the total should sum to 100).

| Assign Points (0–100) | |
|-----------------------|-----|
| Breyer’s | |
| Ben & Jerry’s | |
| Häagen-Dazs | |
| Klondike | |
| Turkey Hill | |
| Total | 100 |

- 4. *Q-Sort*: This is a rank order procedure in which respondents are asked to sort a given number of items or statements and classify them into a predetermined number of sets (usually 11) according to some criterion such as preference, attitude, or behavioral intent. Typically, respondents are given cards to sort. This is typically used when there are a large number of items that should be ranked within a short period of time.

The advantage of comparative scaling is that it forces respondents to compare the options and focus attention on the relative merits and demerits of the options being compared. This is particularly useful in situations in which the marketer desires to identify competitive differences between various products and ads. Comparative scales are also particularly beneficial in developing countries with lower education levels and sophistication levels.

One disadvantage is that when the entities being compared are either vastly different or when there is no basis for comparing the entities (e.g., a fruit juice versus a carbonated soda) – the results of this may be inconclusive. Another disadvantage is that as the number of entities (e.g., brands/products) increases, the number of comparisons that the respondent must make also increases. For instance, if there are four brands that must be compared, a total of $(4 \times 3)/2 = 6$ comparisons should be made. This may cause respondents to become bored or tired, which can reduce their ability to discriminate between options.

2 comparative scaling technique

When comparing values on different variables, it is often assumed that differences in scores can be used as an indicator of relative preference. However, there are biases, for example, acquiescence bias or extreme response style bias, which may affect the answers (*see also* SOCIAL DESIRABILITY BIAS; COMMON METHODS BIAS). Acquiescence bias is the tendency for a respondent to agree with a response. A set response is the tendency for a respondent to answer a series of questions on a certain direction regardless of their content. Response biases may result in responses that are

similar across all the options that are compared. Comparative scaling methods may reduce these biases by forcing respondents to make explicit comparisons across various options.

electronic scanner services

Frank J. Mulhern

Electronic scanner services capture brand sales data from scanner systems at retail store checkouts and sell that information to manufacturers and retailers. The retail scanner systems read the universal product codes (barcodes) on each item purchased and tabulate information on brand sales. Unlike scanner panels (*see* PURCHASE, SCANNER, AND MEDIA PANELS), which capture data on the purchases of individuals and households, electronic scanner services provide aggregate data for individual store locations, retail chains, and metropolitan areas. The scanner systems provide data with a great deal of detail including brand names, package sizes, and prices.

Two companies dominate the electronic scanner services industry – AC Nielsen (www.acnielsen.com) and Information Resources Inc. (www.infores.com). Both companies collect data from carefully selected samples of retail store locations and conduct statistical analysis to estimate brand sales at the account (retail chain) and market levels. While the primary emphasis is on grocery stores, both companies also obtain sales data from major drug and convenience stores. Data is collected on an ongoing basis and aggregated into weeks to match the retail practice of setting price and promotions on a weekly basis. In addition to selling data, the service providers provide some analytic services such as estimating a brand's weekly baseline (nonpromotion) sales and incremental sales due to price discounting.

Nielsen's SCANTRACK service collects weekly data from over 4800 stores representing over 800 retail chains in 52 market areas in the United States. The most important information provided by these services is the timely tracking of brand sales and brand market share at the point of purchase. The information, which first became available in the 1980s after stores installed scanner checkout systems, has revolutionized marketing mix planning by enabling manufacturers to have precise information on how brand sales and market share are affected by prices, promotions, and advertising.

The availability of scanner data has had an enormous impact on point-of-purchase

marketing, which includes shelf-space allocations and in-store advertising and promotion. Manufacturers use sophisticated statistical procedures to assess the effect of a variety of marketing mix elements including prices, in-store coupons, end-of-aisle displays, retail cooperative print advertising, and digital signs in stores. The statistical analyses reveal the impact of each marketing variable on brand sales and market share, allowing brand managers to better develop marketing practices. Statistical analysis of scanner data also reveals patterns of brand switching, variety seeking, price sensitivity, and promotion response.

Because the electronic scanner services provide information on sales in major cities and other geographic areas, manufacturers can use the data to evaluate the effects of local and regional media advertising. In fact, many manufacturers conduct field experiments (*see* EXPERIMENTAL DESIGN) where they vary advertising or promotion in different geographic areas, then evaluate scanner data on brand sales in those areas to assess the effect of the marketing.

While scanner data is of great value for marketers, it has some significant limitations. The quality of scanner data is quite good, but occasional data-collection errors occur when store clerks are unable to scan a barcode or a data-input error assigns the wrong price to an item. Since scanner data aggregates brand sales in a store, it contains no information on the identity of customers or the basket of products purchased together. Also, there is no information on household purchasing across locations of a single chain or across retail chains. These disadvantages are diminishing as the electronic scanner services move to household-level data made available by grocery store buyer clubs. The premier provider of information from that data is DunnHumby, Inc (www.dunnhumby.com), which pioneered the analysis of household-level grocery purchase data at Tesco in the United Kingdom (Humby, Hunt, and Phillips, 2003).

field work/data collection process

Pamela Grimm

Field work refers to the collection of primary data from consumers or business-to-business customers through survey or observation. Unlike the experimental studies that are generally conducted in a controlled environment, researchers studying marketing often rely on data collected in “the field,” – outside a laboratory and in a more natural setting, such as face-to-face, telephone, or online surveys conducted at the respondent’s residence or in shopping malls. Data may also be collected through observations of the respondent’s behavior in the home or in some other setting such as a retail outlet. Therefore, for the purpose of this section, *field work* is defined as the process of data collection using any one of several survey methods such as face-to-face interviews; telephone, postal, and online surveys; or observation.

Most firms subcontract with other firms for data collection. There are a number of vendors who specialize in data collection, many of them listed in a publication known as *The Green Book*. This is a resource compiled by the American Marketing Association that provides a directory of research vendors. Although contracting the whole research study or subcontracting a part of it, such as data collection, relieves the researcher from the headache of doing the research study or collecting data, not every firm can afford to contract or subcontract the entire, or part of, the research study. It is also desirable for a researcher to have sufficient knowledge of the research and data collection processes to be able to interact intelligently with a subcontractor. As a result, a researcher needs to have a sense of what collecting data for a research study entails.

Once the survey instruments are pretested and revised, the researcher is ready to collect the actual data to test hypotheses or answer research questions. If the survey is conducted by mail using the postal service, the process of mailing out surveys primarily involves manual labor rather than specialized training. Of course, people who are mailing the surveys

need to ensure that each respondent receives the cover letter, questionnaire, incentives (if any), and means of returning the completed survey without incurring any cost (e.g., prestamped envelope).

Online surveys can be “fielded” (i.e., launched) even more quickly than snail mail surveys. Online data collection is typically done through software controlled by a service provider, such as Qualtrics, Survey Monkey, or Zoomerang. All that is needed is a list of valid respondent e-mails for the target population and an online survey.

A field study that is being conducted through an interviewer, either face to face or over the telephone, will require training of the interviewers. Training that might be required could include sampling of respondents, review and practice with the survey instrument, recording of responses, special instructions (do’s and don’ts), and so on. Training of interviewers in a field study is important because of the potential for contamination of data due to a failure to follow the correct data collection protocol. Of course, interviewers could also introduce errors in data owing to both verbal (the way they ask questions) and nonverbal (body language, gender) indicators.

A special concern when conducting a field study must be security. Because this research is typically conducted outside the researchers premises, it is very important that steps be taken to ensure the safety of completed surveys or data files. This is important to protect the researcher’s proprietary information and the respondent’s privacy and any guarantee given of confidentiality of responses.

noncomparative scaling technique

Vanitha Swaminathan

Noncomparative scaling techniques is a set of scaling methods in which each item is scaled independently of each of the others. There are various types of noncomparative scaling techniques such as the graphic rating scale, Likert scale, semantic differential scale, and Stapel scale (*see* ITEMIZED RATING SCALES (LIKERT, SEMANTIC DIFFERENTIAL, AND STAPEL)).

A graphic rating scale involves asking respondents to place a check mark on a continuous line. Only the endpoints of a graphic rating scale are numbered. This type of a continuous rating scale enables respondents to provide a wide range of responses. For example,

Listed in Annexure 1 is a set of attributes. Please evaluate how important each attribute is to you in your decision to purchase of a car. Place an X on the horizontal line to indicate how important each attribute is to you.

The Likert, semantic differential, and Stapel scales are examples of noncomparative-itemized rating scales (*see* ITEMIZED RATING SCALES (LIKERT, SEMANTIC DIFFERENTIAL, AND STAPEL)). In these types of scales, there are discrete points along the scale that are typically either numbered or have verbal labels associated with each of the discrete points.

In a Likert scale (also known as an *agree-disagree scale*), respondents are asked to indicate their level of agreement from strongly agree-strongly disagree on either a five- or a seven-point scale. An example of the Likert scale is given in Annexure 2.

An advantage with the Likert scale (as shown above) is that various scale items can be combined. In the above example, respondents' answers to each of the statements can be combined to form a summated score toward Amazon.com.

The semantic differential scale, originally developed by Osgood, Suci, and Tannenbaum (1957), involves providing respondents with

Annexure 1

| Price | Not important | ----- | Very important |
| Reliability | Not important | ----- | Very important |

five- or seven-point scales with bipolar adjectives at either end. An example of a semantic differential scale is provided below:

Please rate Southwest Airlines on the dimensions as per Annexure 3. (Place an "X" suitably on each).

Semantic differential scales are used in marketing primarily to measure brand or store image. The results from several semantic differential scale items can be combined to create a visual image profile of store or brand image for a given store or brand. An example of such a visual image profile is given below:

Comparing the brand image of Southwest airlines and American Airlines. See Annexure 4.

The advantage of the semantic differential scale is that it allows marketing researchers to visually depict the scores across a variety of entities (stores, brands, and companies). One disadvantage may be that respondents have been shown to favor the middle points of a scale. As a result, extreme positive or negative ends of the scale are not used by respondents. Another disadvantage could be that researchers assume that data derived from semantic differential scales is interval data, although, the above scale could sometimes only have ordinal properties.

The Stapel scale helps measure direction as well as intensity of response. A Stapel scale involves placing a single adjective in the center of an even number of values (e.g., ranging from -5 to +5). Respondents are asked to indicate how close to or distant from the adjective a given stimulus may be. The advantage of the Stapel scale is that it is a simple scale which can easily be incorporated in telephone interviews. Compared to the semantic differential scale, it is easier to construct. An example of a Stapel scale

| –5 |

Please indicate the extent to which Target has a wide product assortment.

If you believe the adjective describes the store accurately, then choose a higher plus number.

If you believe that the adjective does not describe the store, then choose a lower minus number.

In addition to deciding on the type of scale (on the basis of the above description), the researcher must also decide on the following:

1. *Number of scale categories:* The larger the number of scale response categories, the

- more the information. However, having too many categories makes it harder for the respondents to react. Typically, market-research surveys (*see* SURVEY RESEARCH) measure brand attitudes or brand preferences using five-, seven- or nine-point scale categories.
2. *Odd/Even number of response categories:* A key decision that a researcher has to make is whether to have odd/even number of response categories. Choosing an odd number of response categories can help respondents by providing them a midpoint, which can help capture “neutral” responses. An even number of response categories forces respondents to provide a directional response, and may sometimes artificially force neutral respondents to skew their responses to suit the scale.
 3. *Balanced versus unbalanced scales:* A key decision is whether the questions have to have equal number of favorable or unfavorable responses. In unbalanced scales, there are an unequal number of favorable and unfavorable response categories.
 4. *Forced versus nonforced scales:* In forced scales, the respondents cannot have the option of expressing either “no opinion”

Annexure 4

Comparing the brand image of Southwest airlines and American airlines

Southwest airlines: - - - -

American airlines: _____

or “do not know” in response to a question. Forced response scales may be problematic in cases where a large number of respondents have insufficient knowledge to respond.

5. *Nature and degree of verbal descriptors*: Verbal descriptors are particularly helpful to respondents since they enable them to articulate the responses better. However, researchers must exercise care in ensuring that verbal descriptors are unambiguous and accurately reflect the response categories.

nonprobability sampling

Richard J. Fox

Nonprobability sampling entails judgmental selection of a subset from a population in such a way that the subset selected is not dictated by chance or randomness. Sampling is performed to learn about a population, but when nonprobability sampling is used, generalizing the results to the entire population is questionable. Further, the statistical methods related to measuring the precision and accuracy of estimates derived from the sample are no longer valid. However, nonprobability samples can be useful for gaining general understanding about how a population behaves, how opinion on a topic varies from individual to individual, and so on.

There are a number of types of nonprobability sampling (see Malhotra (2007) for a discussion of nonprobability sampling techniques). As the name suggests, a convenience sample is one that is convenient to the individuals selecting the sample. For example, a college student might question his or her friends about a movie that they have seen in order to determine whether he or she might be interested in seeing it. A company might enquire from its major clients, namely, those with whom the company does considerable business, what they think of a new billing procedure. Student samples, often used by university professors in academic research, are also convenience samples.

Judgment sampling is another form of nonprobability sampling. In this case, the investigator or individuals seeking the information about a population subjectively choose members from the population to compose the sample. For example, business managers might decide to interview large customers regarding their plans for the next fiscal year. The rationale is that information from large customers is critical to planning for the coming year. Product engineers in a software company may choose to talk to the “lead users” of the various software tools that the company markets. The reasoning is that future development will likely be driven by these lead users.

Snowball sampling, another form of nonprobability sampling, involves asking individuals initially selected to be in a sample to provide

contact information for others to be potentially included in the sample. This is a particularly useful tool when looking for individuals whose incidence is very low. For example, to obtain a sample of individuals with extensive hiking experience, a person who qualifies could be asked to provide contact information regarding others who have similar interest or expertise.

A self-selecting sample is also a form of nonprobability sample. In a self-selecting sample, individuals “volunteer” to be in the sample. For example, cell phone text polls provide a vehicle for individuals to “text” a vote for one of two or more options. The votes are tallied and the winner announced during the event or broadcast in which the poll is conducted. The only people included in such a sample are those who choose to participate. These are likely to be individuals who have a vested interest in the topic, and hence are not necessarily a representative sample of the population. Even if the number of responses obtained is extremely large, the validity of the sample is still in question. In a large study of adults in the United States, the majority of people reported that polls of this type are valid because many people participate. Again, this is a misconception. The sample size may be large but the sample may be far from representative.

Finally, another form of nonprobability sampling is quota sampling. In this instance, restrictions are placed on the sample so that the numbers of sample units classified into specific categories meet prescribed requirements. For example, the sample may be required to be half male and half female, or to match the US age distribution. However, there is no assurance that the sampling method used to meet each quota requirement is such that representative samples are selected for the quota groups. Convenience samples might be used to fill the quotas. Hence, estimates relating to individual quota groups as well as overall estimates are not valid, and their accuracy and precision cannot be determined.

personal observation

Linda L. Price

Observational approaches have a long history in social science including marketing and consumer research. Broadly speaking, observation methods include all data collection in which participants are not asked to give us data, but rather are monitored for data. Observation can be quantitative (such as head counts or measurements of wear or use) or qualitative (such as participant observation or netnography) (see OBSERVATION METHODS). *Personal observation* is a subset of observational approaches in which the researcher is the primary instrument for monitoring participants. For example, studies that use technologies to measure participants' physiological responses to stimuli are observational, but not personal observation. Nonetheless, reliance on technology for personal observation is often substantial. For example, videotaping, cameras, websites, and so on are commonly employed in fieldwork by ethnographers and netnographers. What distinguishes personal observation from other observational methods is that the researcher views the videos, examines the pictures, and visits the community websites in order to collect relevant data and then interprets and represents it in study findings.

Personal observation can be covert or overt, participatory or nonparticipatory and varies in how obtrusive it is in participants' lives. For example, a researcher may seek entry into an activity or community with the explicit aim of doing research (overt), may participate in the practices of that community (participatory), and as a consequence, may change that community in some ways (obtrusive). Alternatively, the researcher may place cameras at a location in a store (overt), observe customer behaviors at that site from a distance (nonparticipatory) and leave participants' unaware of researcher presence (nonobtrusive). In practice, researchers would often employ a mix of participatory and nonparticipatory observations during their fieldwork (see FIELD WORK/DATA COLLECTION PROCESS). Personal observation can be more or less systematic in terms of sampling and recording, but should always involve detailed field notes or tallies recorded as close

to the moment of observation as possible. By immediately recording observations researchers avoid memory biases that could lead them to selectively remember and forget, generally in ways that systematically conform to their cultural expectations.

Although personal observation can be quantitative or qualitative, in marketing and consumer research it is most often associated with ethnographic research, a qualitative technique. In fact, participant observation is generally considered the central and defining feature of ETHNOGRAPHIC RESEARCH. *Participant observation* is a systemic recording and analysis of information gained while engaged in and observing activities, rituals, interactions, and events in order to uncover explicit and tacit aspects of the field of study. The approach that ethnographers use in participant observation is highly individualistic affected by a complex mix of context factors, theoretical frameworks, and personal characteristics. Participant observation is both a data collection and an analytic tool, since participating in activities and events in the field provides researchers with a tacit understanding that shapes both observations and subsequent interpretation of data collected. Multivoiced participant observation that uses multiple researchers in the field participating and observing the same or similar activities, practices, and events can uncover a fuller array of perspectives and often provide a more integrative and complete narrative account. For example, multigendered teams can help give voice to both female and male lived experiences. Member checks and the use of multiple types and sources of data can also increase the perceived trustworthiness of the researcher account. A number of different criteria might be used to evaluate the trustworthiness of the observational account including adequacy, resonance, integration, innovation, and usefulness (see RESEARCH RELIABILITY AND VALIDITY).

Personal observation raises many important ethical issues for researchers. These issues include establishing limits to participation, finding the proper mix of observation and participation, and maintaining the anonymity of informants' studied. As with other social science research, a good starting point is to work to

2 personal observation

ensure that people studied are not harmed by researcher involvements or negatively affected by the information collected and written about them (see ETHICS IN MARKETING RESEARCH). Some researchers adopt a critical ethnography or action research perspective and advocate the explicit goal of improving human well-being through participatory research (see CONSUMER WELL-BEING). For example, they might argue that the studied community should be the source of research problems and the primary beneficiary of the research.

Pretesting a questionnaire

Pamela Grimm

Pretesting or pilot testing of a survey is conducted to test the survey instrument and data collection procedure before data collection begins. The objective is to ensure that the questions being asked accurately reflect the information the researcher desires and that the respondent can and will answer the questions. In general, the types of problems that may be encountered in a survey range from misinterpretation of questions to the inability or unwillingness to answer questions or to the length of time required to respond. The number, wording, and layout or ordering of questions may be the root cause of many survey problems.

Pretesting should be considered a critical step to go through when collecting data via a survey. Failure to pretest could increase both the sampling errors (because of nonresponse to either a few questions or the whole questionnaire) and nonsampling errors (because of misunderstanding some questions, incorrect or unclear skip patterns, or any number of other reasons). Pretesting of the questionnaire should replicate, as much as possible, the way the final study will be conducted. Pretesting is usually done on a small sample (about 30) that matches the characteristics of the population that will be sampled for the study. However, less formal pretesting can be conducted with a smaller convenience sample.

Typically, the researcher will ask the respondent to complete the survey and then ask the respondent questions, either one-on-one or in small groups, during a debriefing session. If the survey was administered by an interviewer, as would be the case for telephone or mall intercept surveys, interviewers also are debriefed. An alternative to debriefing after administering the questionnaire is to have respondents "think out loud" while filling out the questionnaire. Both mechanisms provide the researcher with a respondent's reaction to the questionnaire.

While the emphasis is often on qualitative feedback during a debriefing session, it is also important to tabulate the data collected

though the pilot test and examine the patterns of responses to each question, looking for questions that respondents are refusing to answer, incorrectly skipping, or which seem to be misinterpreted. These data, however, are not included with the data collected later in the final survey.

More specifically, the researcher addresses the following items in a pretest:

1. Did the respondents clearly understand what was being asked and the terminology being used?
2. Was there any major option missing in any of the questions? If several respondents write new option(s) to a question, options are obviously not exhaustive.
3. Was the respondent willing to answer each question? Were any questions offensive, sensitive, or too difficult?
4. Did the respondent understand the instructions for responding to each question? For example, instructions may not be clear regarding choice of only one option or multiple options to a question.
5. Did the respondent feel that the researcher wanted him or her to answer in some specific way (i.e., did the respondent feel some of the questions were biased)?
6. Did the respondents understand any instructions regarding skipping questions depending upon the answer to previous questions?
7. Did the flow and language of the questionnaire seem logical and natural?
8. Did the time taken to answer the questionnaire seem reasonable?
9. If the survey was administered by an interviewer, did the respondent feel that the interviewer, either verbally or nonverbally, tried to bias his or her response?

This is a short list of areas that the researcher might check during a pretest. Once the pretest is complete, any changes necessary should be made. If changes are substantive, the researcher may want to engage in a second round of pretesting. More details on pretesting questionnaire can be found in QUESTIONNAIRE DESIGN.

primary scales of measurement

Frederick Winter

Scales in marketing are similar to the trusty ruler. They are used to measure things. But unlike a ruler, which is much like another ruler, different scales are used by marketers to measure different things. It is crucial when using market research to look at data and understand the scale as well as some properties that led to the data that one is viewing.

Scales can be of the following types: nominal, ordinal, interval, and ratio based. The order described also shows the increasing data content as one goes from nominal up to ratio. At the low end of the scale, is a nominal scale that comes from the Latin word *nomen*, which means “name.” The most common example of a nominal scale is the number on a football jersey. Marketers use nominal scale in a number of ways. For example, we could describe the consumer’s favorite brand of cereal, and that would represent nominal data. We could indicate the consumer’s preferred store where he/she would buy a product. That too would be nominal. There are a lot of statistics that we are used to using such as the average, which are no longer meaningful when we have nominal data. Let us say five consumers bought Cheerios, three consumers bought Frosted Flakes, and two consumers bought Grape-Nuts. The average brand that the group bought makes no sense. Rather some statistic that indicates the norm is the *mode* – which is the most frequently occurring value. In our cereal example, we would say the mode is Cheerios since it is the most frequently occurring value. Nominal data can also be analyzed in terms of the relationship between two or more nominal variables. For example, one might want to know if the preferred breakfast cereal is related to gender, another nominal variable. A common method used by marketing researchers is CROSS-TABULATION which reports joint frequency; association can be tested using the chi-square test statistic to indicate if there is such a relationship between two nominal variables.

If we have asked the consumer to rank order his/her preference for stores we would have

an ordinal scale. Ordinal scales contain more content than do nominal scales because it says that something ranked 1 is higher (or lower) in attribute than something that is ranked number 2 and 2 is more (or less) than something ranked 3. Ordinal scale, as the name implies, indicates something about order. (as indicated 1 could be high – such as weight, or low – such as lightness). With ordinal data, there is no implication of the distance between the data. Like a running race, the difference between first and second place might not be the same as the difference between 40th and 41st place. Theoretically, we can report the mode on ordinal data, assuming it is not place in a race (where everybody has a unique value and all places qualify as the mode). Quite often, we summarize the central tendency with ordinal data in terms of the median in which half of the numbers fall above and half below. We can also associate two or more ordinal variables using cross classification, but the techniques available are a little more powerful because the data are more powerful and we can use things like the Spearman rank order correlation coefficient to indicate a relationship between two or more variables.

The data content increases considerably as we go from ordinal data to interval data. In interval data the difference between 1 and 2, which is 1, is the same as the difference between 41 and 42. Given this property, some of the very familiar statistics that we are used to, such as the mean (average) now becomes a relevant measure of centrality. If we are willing to assign interval data into categories (e.g., 1–5, 5–15, 16– and up) we can still use cross tabulation to check association between two variables. However, the new power inherent in the data allows a whole new series of analyses where we look at association between variables using some form of correlation (see PRODUCT MOMENT CORRELATION).

With interval data the difference between 22 and 27 is the same as the difference between 5 and 10. So, what do ratio data have that interval data do not? With ratio data, the value of 0 has a meaning in it that means nil, or nothing. Clearly, with the Fahrenheit scale a temperature of 0 does not mean 0 or nothing. The number of boxes of Cheerios consumed in a year would be a good example of a ratio scale. For all but the

2 primary scales of measurement

most esoteric considerations such as a geometric or harmonic mean, ratio scales do not really provide much by way of practical value than interval scales.

Scales selected are important because they define the properties of the measurements that dictate the analyses that are possible subsequent to data collection. Where possible, marketers should try to collect interval data unless only ordinal data or nominal data fit the situation.

Much of marketing is all about association between variables, where we might then make causal inferences. Many techniques exist that relate mixes of nominal, ordinal, and interval scaled data. For example, if we have an

intervally scaled dependent variable that we think is dependent on one or more nominally scaled independent variables, we might use MULTIPLE REGRESSION, a correlation technique, by converting nominally scaled data into dummy variables.

probability sampling

Richard J. Fox

The purpose of sampling is to select for analysis a subset of the population to make inferences about the entire population (typically a large group). The population can be people, households, geographically defined areas, manufactured items in a warehouse awaiting shipping, and so forth. Measurements associated with items in the selected subset are used to develop estimates of descriptive statistics for the population such as the mean, mode, and standard deviation. Statistical assurance regarding the integrity of these estimates as well as the associated precision calculations is based on the assumption that probability sampling was used to select the sample. This is a crucial assumption, but it is often overlooked in practice.

Probability sampling refers to any method of selecting the subset of the population that comprises the sample in such a way that each element of the population has a positive probability of being included in the selected subset. Suppose the population contains N elements, and the sample contains $n < N$ elements. If the selection process is such that all subsets of size n are equally likely to be the sample selected, the process is called *simple random sampling*, a form of probability sampling. The probability of any element being selected in the sample is n/N . In most situations N is large, and even for relatively small values of n there are many possible subsets. Consequently, the number of possible estimates of any specific population characteristic of interest can also be very large.

Suppose an estimate of the average income of all N households in a specific geographic region is desired, based on a sample of size n . The sample average based on the n selected households in the sample is an estimate of the mean for the entire population. The value of this estimate varies from sample to sample. If simple random sampling is employed, then the average value of the individual sample means associated with the numerous possible samples is, in fact, equal to the population mean. In statistical language, the estimate (sample average) is said to be unbiased. Furthermore, if simple

random sampling is used, one can readily calculate the 95% confidence interval (\pm error limits) from the sample data. There is only a 5% chance that the actual population mean is not contained in this 95% confidence interval, which provides insight into the precision of the estimate. These intervals can be calculated at alternative confidence levels (e.g., 90% or 99%). As the level of confidence increases, so does the width of the calculated interval. Also, as the sample size increases, the width of the confidence interval decreases for a fixed level of confidence (see STATISTICAL APPROACHES TO DETERMINING SAMPLE SIZES). Finally, the width of the confidence interval increases as the variance of the measurements associated with the sample elements increases.

There are other forms of probability sampling including *systematic sampling*, *cluster sampling*, and *stratified sampling*, (see Cochran (1977) for a thorough discussion of these sampling methods), which are more sophisticated than simple random sampling. The calculations of the estimators and the associated levels of precision vary with the type of probability sampling used, and can become quite complicated. These alternative forms of probability sampling can increase efficiency and cost effectiveness, and are sometimes preferable because of practical considerations (see SAMPLING TECHNIQUES).

In summary, it is important that probability sampling be employed when selecting a sample from which inferences regarding a population are to be made. Only then can statistical theory be used to guarantee integrity (unbiasedness) of the estimates and determine the precision of the associated estimates. Too often, samples are selected without using a probability sample, and statistical methods are still used to establish the precision of the subsequent estimates. Estimates derived from such samples can be useful, but traditional statistical precision calculations are not applicable.

projective techniques

Linda L. Price

Projective techniques are characterized by substantial methodological heterogeneity that presents both research opportunities and challenges. Classically, projective techniques use stimuli to allow the research participant to articulate repressed or withheld feelings by projecting these onto another character or object. However, many researchers also group enabling techniques with projective techniques. Enabling techniques are devices that allow the research participant to find a means of expressing feelings, thoughts, and so on that they find hard to articulate. In marketing research, the distinction between projective and enabling techniques is often blurred and they are used similarly (see MOTIVATION RESEARCH). In this description they are combined.

Despite high variance, there are distinct similarities among projective techniques both in the nature of the research stimuli and the type of data elicited. Projective techniques typically rely on *indirect questioning*, and *ambiguous stimuli* that allow for nearly limitless variations in informant responses. For example, consumers might be asked to construct collages to represent their desires, describe dreams involving fast food, characterize a typical target shopper, or draw a “couch potato.” Projective techniques can uncover *primary motives* as well as *latent motives* that consumers might otherwise be unwilling or unable to articulate. In addition, they tend to elicit data that compared with many other research approaches is more *sensory*, *emotional*, *symbolic*, *metaphorical*, and *imaginative*. Finally, projective techniques are relatively *free of social desirability bias* (see SOCIAL DESIRABILITY BIAS). The indirect questioning and ambiguous stimuli give informants the opportunity and permission to express their true and deeper level concerns.

Projective techniques have their historical roots in clinical psychology and have been the target of critical debate and scathing criticism as tools for patient diagnosis, treatment, and prescription because of justifiable concerns about their reliability and validity for this type of use. Partially in response to these kinds of concerns,

projective techniques passed out of popular use in marketing and consumer research in the 1970s and 1980s. However, there has been a resurgence in attention and use encouraged by theoretical interests in consumer’s emotions, desires, motivations, brand meanings, and relationships all of which are well suited to examination using projective techniques (see CONSUMER DESIRE; MOTIVATION AND GOALS). In market and consumer research, projective techniques are primarily used to discover new ideas, broaden customer understandings, and generate new market offerings, brand positions, or communications. They are more likely to be employed in theory building than testing and are rarely used exclusively, but most often in combination with other methods such as depth interviews or surveys (see FOCUS GROUPS AND DEPTH INTERVIEWS; SURVEY RESEARCH).

As with other primarily interpretive methods, the skill and experience of the researcher is paramount in constructing a trustworthy account. Several criteria can be employed to ensure the trustworthiness of the interpretation including adequacy, resonance, integration, innovation, and usefulness. To enhance reliability and validity, researchers may triangulate across different types of data or may elicit member checks from participants following researcher interpretations. Some argue that because projective techniques enable participants to express themselves in fuller, more subtle, and fairer ways (without the constraints of direct questioning) they may actually achieve greater validity than other methods (see RESEARCH RELIABILITY AND VALIDITY).

In deciding whether the use of projective techniques will add value, researchers should consider consumer memory, communication, and self-disclosure concerns (see CONSUMER MEMORY PROCESSES). For example, the use of story telling, dream exercises, autodrawing with personal photos, and collage construction can help consumers recall and/or help them retrieve the emotionality or meaning of a consumer episode. Projective techniques that rely on nonverbal expressions such as picture drawing or collages can sometimes facilitate consumer articulation or encourage elaboration. And, of course, when consumers are reluctant to

2 projective techniques

disclose or inclined to lie, projective techniques may add significant value.

Projective techniques differ both in the quantity of data they elicit and in their response modality. With regard to quantity of data, techniques such as word association, sentence completion, or cartoon tests elicit relatively little raw data per informant while collage construction, dream exercises, autodriving, thematic stories, and psychodramas elicit a large amount of raw data per informant. Modality of response can vary from short written/verbal responses to lengthy verbal/written narratives, and from brief visual associations such as symbol matching to complex visual constructions such as collages and drawings. Responses may also take a physical/body language form such as when informants role-play in a psychodrama. By including projective techniques that vary in modality and quantity of response, researchers may be able to increase their interpretive opportunities.

validity and reliability

Frederick Winter

When we take measurements we want them to mean something. Assume a person wants to get healthy, and therefore wants to lose weight. He or she would get pretty discouraged with his or her weight loss program if the bathroom scale is so unreliable that the weight fluctuates significantly from day to day – not because of gravitational pull (the person's true weight) but because the scale is erratic. We would call this the *issue of reliability*.

We quite often put consumers into experimental groups for analysis (*see* EXPERIMENTAL DESIGN) when some of this unreliability of measurement might seem tolerable. For example, one group of consumers eats vegetables and gets lots of exercise and the other group eats at McDonald's and watches TV all day. When we compare the two groups, even with an erratic scale, it is expected that the differences would tend to cancel out and we would still see the vegetable-exercise group make progress? Perhaps this may happen, but we must remember that significance tests generally look at the difference between two means divided by the variance, and, if the unreliable scale increases the variance, we are less likely to detect a significant difference when one might really exist. Marketers improve their reasoning ability from data when they use reliable measures.

Marketers are able to assess reliability in a number of ways. One method is the *test-retest reliability*. Measure something and then remeasure it again. When it is reasonable to assume nothing has changed, we should get close to the same measurement. The simplest and most common way is to calculate a simple correlation coefficient (range -1 to $+1$) between the two measurements (*see* PRODUCT MOMENT CORRELATION). High correlation suggests reliability.

Another method is *split half reliability* where half the measures that claim to measure the same attribute in one subsample are correlated with the other half of the measurements that measure the attribute in the other subsample. *Coefficient alpha* (Cronbach, 1951 – see the original reference for the more generalized formulation) is the

correlation between the two halves. When alpha is high, the measures are reliable. In the split half case (two subsamples), alpha is calculated as

$$\alpha = 2 \left[1 - \frac{(\sigma_1^2 + \sigma_2^2)}{\sigma_{1+2}^2} \right] \quad (1)$$

where σ_x^2 is the variance of variance of subsample 1, 2 or the combined subsamples (1 + 2). Although the formula does not look intuitive, recall that the variance of a two-term sum is the variance of each component plus two times the covariance (correlation). If correlation between the subsample is 0, the last term will equal 1, and $\alpha = 0$. If correlation equals 1, the last term will equal $1/2$ and $\alpha = 1$.

What about validity? Marketing is unlike the physical sciences where there exist precise definitions of weight/mass, distance, and so on. We measure how much someone likes something, a construct, with operational definitions – measures that we take – perhaps on a 1–5 numerical scale. Using our first example, a health professional might say that weight relates to overall health, but it is not a perfect measure. This is the issue of validity. Is weight and weight loss a good indicator of health? Marketers generally consider face (or content) validity, criterion (predictive/concurrent) validity, and construct validity as ways in which to make sure that their measurements are valid.

Face validity or content validity is based on a subjective judgment as to whether it makes sense that what we are measuring indeed represents the underlying construct we are trying to measure. One rule of thumb is to observe how others have chosen to measure it and depart from this only if it seems to make great sense. Let us say we are trying to measure sales force effort – is it simply the number of calls? The number of calls really does not consider the territory size, distance that has to be traveled, difficulty of getting an appointment with the customer mix in the region, and so on. More than likely we might want to use a weighted combination of some of the above and that would likely result in more content validity.

Criterion validity is where the researcher has a theory with which he or she is pretty comfortable and which involves that which is being

2 validity and reliability

measured. The researcher then makes sure there is correlation (concurrent validity if the measurements are expected to correspond at the same point in time and predictive validity if one measure is expected to relate to another at a later point in time). For example, if the measure of salesperson effort is known, the researcher would then correlate it with sales performance, since he or she is somewhat comfortable with the conclusion that more effort should result in greater performance. Of course, the problem is that other things might contribute to sales performance that the researcher would attempt to hold as constant – either statistically with some form of analysis of covariance or step-wise regression or perhaps by controlling with sampling. For example, experience could be held constant by simply testing whether the measure of sales effort predicted sales among salespersons in their fourth year of employment.

Construct validity is the most difficult to measure and less precise when one does. This is where the researcher makes sure that he or she is really measuring the construct that he or she reports to be measuring. Let us say part of our theory is that wealth affects purchasing behavior. If our measure of wealth has construct validity, then we might expect it to have criterion

validity with some known other factors that we know wealth relates to (having an estate plan, using tax accounting services, value of real estate held, etc.) and it probably would be uncorrelated (discriminant validity) with some other measures that we know to be unrelated to wealth (it should be uncorrelated with happiness if it is well established that wealth does not relate to happiness). In short, does it fit as we would expect it to fit?

Reliability and validity interact to produce measurements in which we can have confidence – valid measures are reliable, but reliable measures are not necessarily valid (they might be reliably measuring another construct). However, if measures are not reliable, they cannot be valid.

social desirability bias

Pamela Grimm

Social desirability bias refers to the tendency of research subjects to choose responses they believe are more socially desirable or acceptable rather than choosing responses that are reflective of their true thoughts or feelings. This tendency results in over-reporting of responses that are socially desirable and under-reporting of those responses that are deemed to be socially undesirable/less desirable. This tendency is believed to be a personality trait based on the subject's need for approval. Social desirability bias may become an issue when research involves collecting data on personal or socially sensitive issues. For example, respondents may believe that society expects them to be responsible for the environment, even though the respondent may not care much about the environment. In such a situation, the respondent may simply indicate an environmentally conscious attitude rather than choose an option that represents his or her true feelings. The idea of "political correctness" is based on social desirability bias.

The problem of social desirability bias is most likely to occur in those situations in which questions relate to what are widely accepted attitudes, or behavioral or social norms (e.g., smoking, drug use, lying, cheating, and protection of environment). This bias is reported to be most apparent when data are collected through a survey method where the respondent can be easily identified. For example, social desirability bias may occur when collecting data through personal interviews, specifically because of the presence of another individual. Collecting data through a mechanism that allows for privacy may decrease social desirability bias. For example, a mail survey may be least susceptible to such bias because of the impersonal nature of responses and the ability of the respondent to submit the survey anonymously. Reassuring subjects that their responses will be kept confidential or anonymous should also help minimize social desirability bias.

The concept of social desirability bias is also related to a concept termed *demand effects*. The

idea behind demand effects is that the subject responds to a question in the way he or she believes the researcher desires. Demand effects are specific to the researcher and may or may not reference the subject's beliefs about what society as a whole believes about a specific topic. Careful design of a survey or focus group outline, which avoids leading questions, should be able to minimize or reduce demand effects.

Recent research on social desirability bias indicates that this bias may not be as prevalent as previously believed. Part of "intentional misrepresentation" may actually be attributable to accidental mistakes in recall (Krosnick, 1999, p. 546), rather than intentional lying.

Researchers have suggested a number of actions to address this issue (Nederhof, 1985). If the length of the survey permits, it is advisable to measure the social desirability bias by administering the social desirability scale. This allows the researcher to assess the extent of the problem of social desirability influence in survey responses. A properly designed survey could also help mitigate this problem. For example, in the case of questions that are prone to generate "socially desirable" responses, it is important to provide response options to such questions where the respondents have the opportunity to tell the truth. One of the sources of social desirability influence is the interviewer himself/herself, whereby the respondents try to "please" the interviewer by guessing what are "acceptable answers." When possible, collecting data through mail surveys rather than telephone or face-to-face surveys tends to reduce the social desirability bias. If it is necessary to use other modes of data collection using an interviewer, then it is advisable to use professional interviewers.

concept of causality and conditions for causality

Harmen Oppewal

Figure 1 A true causal relationship between *X* and *Y*.

Causality concerns relationships between variables where a change in one variable necessarily results in a change in another variable. Philosophers have debated for centuries whether there is such a thing as causality. Can we ever know the true causes of anything? Empiricists like the eighteenth-century Scottish philosopher David Hume argued that all we can see are the observable associations between events (Dunbar, 1995). Causes are only in our minds and we can never be sure they really exist. Nevertheless, causal knowledge is one of our most powerful resources because it tells what can or should be done to obtain a desired consequence or to avoid an undesirable outcome (Shadish, Cook, and Campbell, 2002). Causal knowledge is especially useful if it includes knowledge about the effects of variables that we have active control over – in marketing these are the typical marketing mix variables such as price, promotion, place (location and distribution), and, of course, the actual product.

THREE REQUIREMENTS

There are *three requirements* for a causal relationship, according to John Stuart Mill, a nineteenth-century English philosopher. In general, as shown in Figure 1, the question is when is *X* a cause for *Y*? Firstly, there has to be covariation: if *X* varies then *Y* should vary too. If there are clouds (*X*), then it may start raining, but if there are no clouds, it should not rain – or we would be very surprised, as it violates a basic piece of causal knowledge that is well ingrained in our shared understanding of how things work in our world: clouds are a prerequisite for rain. Similarly, in marketing we generally expect promotions to have at least some effect on sales and would be surprised (if not disappointed) if variations in promotional activities did not correspond with at least some variation in sales.

Secondly, there should be a sequence in time: First *X* changes, and then *Y* changes. We would be very suspicious if it first rained and clouds would appear only later. For promotions and

sales levels, this relationship is more complicated as many different factors drive sales. Our challenge is to disentangle the variation due to other factors from the variation that we expect to occur due to promotion; once we achieve this, we expect variation due to promotional activity only to occur after the campaign has started. In contrast, if *Y* changes without *X* changing or before *X* has changed, we must conclude there is no causal relationship.

The third requirement is the most difficult to determine: No other, or “third variable,” should covary with *X* and *Y*. A “*third variable*” is a variable, possibly yet unidentified or unobserved, that might be the true cause for changes observed in two other variables of interest. If there were a variable *Z* that varies with *X* and *Y*, *Z* instead of *X* could be the true cause for the variation observed for *Y*. This relationship is shown in Figure 2. In the rain example, this would mean that, whereas we may have recorded heavy clouds overnight, we cannot be sure the increased water levels in a stream are due to rain or are the result of melting snow upstream. Similarly, there may be other factors driving increases in sales at the same time as we introduced our campaign. Although the sales increase coincides with the introduction of the campaign, it is well possible that the campaign has no real effect because the increase is caused by other factors such as a change in competitor activity or a seasonal effect like the start of the holidays. In this case, if the campaign content is linked to a season like Christmas or back to school, there is a double causal relation between the season and the change in the studied “cause” and the observed effect. In this case, the relationship between having a promotional campaign (*X*) and observed sales (*Y*) is completely *spurious* because both variables directly depend on the start of the holiday season (*Z*) and a conclusion that the campaign causes sales to increase is false.

Alternatively, the true cause may indeed be the promotional campaign, but this leaves the question unanswered as to what was the “active

2 concept of causality and conditions for causality

Figure 2 A spurious relationship between X and Y .

ingredient” that made the promotion a success. Was it the media coverage, or the type of promotion, or the role of imagery or type of appeal? Or were these “ingredients” all strictly required to make the promotion achieve the observed sales effect?

CONCLUSION

In sum, causal knowledge is valuable but difficult to attain. Not only are there alternative explanations, often we are not sure what exactly the “active ingredient” is in our observed causes.

This is a crucial but often underestimated issue in applied research. Indeed, too often researchers spend a lot of time developing, implementing, and analyzing a design without careful consideration of the essential question: what do we think we are studying and does it match what we are actually studying? This is the question of construct validity (see VALIDITY IN EXPERIMENTATION; RESEARCH RELIABILITY AND VALIDITY).

confirmatory factor analysis

Richard J. Fox

INTRODUCTION

The basic factor analysis model is a representation of relationships between a set of observed variables, all of which are manifestations of a smaller set of unobserved latent variables or factors. Each observed variable is a linear combination of the unobserved latent factors, which may or may not be correlated, plus a random error term, also unobserved. The random unobserved error terms can also be correlated, but are independent of the unobserved latent factors. The coefficients of the latent factors are called *factor loadings* and they reflect the degree of association between the corresponding latent and observed variables. The matrix equation displaying the covariance matrix of the observed variables (left-hand side of the equation) as a function of three matrices, the matrix of factor loadings, and the covariance matrices of the latent variables and the random error terms, is called the *covariance equation*.

The model has a large number of unknown parameters, all elements of the three matrices appearing in the right-hand side of the covariance equation, and constraints must be imposed to reduce the number of parameters to be estimated. Selected pairs of latent variables or random error terms can be assumed to be independent (zero covariance). Each latent variable may be assumed to manifest itself in only a specified subset of the observed variables (i.e., selected factor loadings are set equal to zero). Also, equality of variance constraints may be imposed among the errors or latent factors.

IDENTIFICATION

Constraints are imposed for the purpose of model identification (see Long's *Confirmatory Factor Analysis* for a discussion of model identification), which means that a unique set of parameter estimates will be obtained for the constrained model. If a model is unidentified, an infinite set of possible model parameter estimates produce the same covariance matrix for the observed variables. If the model is

identified, estimation can proceed. A random sample of the observable variables is used to develop a sample covariance matrix, and maximum likelihood methods are typically used to estimate the model matrices (the three matrices described above) under the imposed constraints. The estimates of the model matrices are chosen so that the matrix formed by applying the covariance equation, using the estimated matrices, produces a covariance matrix that is as "close" as possible to the sample covariance matrix. Finally, the estimated covariance matrix corresponding to the constrained model is compared to the sample covariance matrix to determine whether the structure imposed by the model assumptions and constraints is consistent with the data. The chi-square goodness-of-fit test is used to compare these two matrices. The larger the difference, the larger the chi-square statistic. A relatively "small" chi-square "confirms" the structure resulting from the model constraints; a relatively "large" chi-square value leads to rejection of the assumed model. This is the essence of confirmatory factor analysis.

EXAMPLE

Consider as an example, the SERVQUAL Scale, developed by Zeithaml, Parasuraman, and Berry (1990) designed to measure the gap between customer quality expectations and perceived delivery of key service dimensions. The RATER version of SERVQUAL focuses on five dimensions of service quality: reliability, assurance, tangibles, empathy, and responsiveness. To compute a SERVQUAL score, survey participants (customers) first rate their levels of agreement for a list of over 20 statements reflecting expectations related to the five core service dimensions. (The rating exercise is repeated in the context of service provider performance delivery, and the gap is measured by comparing expectations to delivery). The set of over 20 item ratings constitutes the set of observed variables, and the latent factors are the five service dimensions. Early development work associated with SERVQUAL was designed to investigate the relationships between the list of statements and core service dimensions. For example, can the list of statements be reasonably

2 confirmatory factor analysis

partitioned into five mutually exclusive and exhaustive sets? If each statement in the list can be associated with one, and only one, of the core dimensions, then each dimension can be viewed as an aggregate of a subset of list items. This question can be addressed using confirmatory factor analysis.

In the SERVQUAL example, the use of five mutually exclusive and exhaustive sets of statements reflecting five core service dimensions implies that many of the factor loadings are zero. In addition, the five latent service factors can be assumed to be independent, and so on. A sample covariance matrix is calculated from a random sample of respondents' ratings of the list of over 20 items. The three matrices of the covariance equation, suggested by the assumed data structure, are estimated using maximum likelihood applied to the same random sample of respondents ratings. The estimated covariance matrix obtained by applying the covariance equation using these three estimated matrices is then compared to the sample covariance matrix. If the two covariance matrices are "close," the hypothesized data structure for the observed variables (ratings) is consistent with the data.

STRUCTURAL EQUATION MODELS

Confirmatory factor analysis is also often a critical component of what is referred to as *structural equations modeling*. In this type of model building, a causal relationship is presumed to exist among a set of latent factors. These latent factors manifest themselves through a set of variables that are possibly measured with error. Confirmatory factor analysis is used to develop a measurement model for the unobserved latent variables, which are the basic variables in the causal relationship being explored.

EXPLORATORY FACTOR ANALYSIS

Confirmatory factor analysis might also be used in conjunction with exploratory factor analysis (see *Applied Multivariate Research Design and Interpretation* by Meyers, Gamst, and Guarino (2006) for a discussion of exploratory versus confirmatory factor analysis). For example, exploratory factor analysis might be applied to half of the sample data to develop a model relating latent factors to observed variables. The exploratory analysis would determine how many underlying latent factors there are, as well as which factors influence which observed variables. Confirmatory factor analysis can then be used on the other half of the sample to determine how well the model fits this independent data set. The observed covariance matrix for this "hold-out" sample would be used to assess how well the structure imposed by the model derived by exploratory factor analysis fits an independent data set.

content analysis

Linda L. Price

Content analysis is a general term for techniques that *systematically* identify and evaluate the symbolic content of communications (images, words, etc.). It can be effectively employed to examine virtually any type of communication and may focus on either quantitative or qualitative aspects of messages. While some interpretive researchers dismiss content analysis from discussion of qualitative methods emphasizing it is quantitative, others argue for expanding the term and its application to include accounts of communications not in the form of numbers and not restricted to frequency counts. Quantitatively, researchers can create tally sheets to determine frequencies of relevant categories in the way that content analysis is typically employed. Alternatively, researchers can qualitatively examine themes, topics, symbols, and other phenomena while systematically grounding such examinations in the data.

Content analysis of text is distinct from a hermeneutical approach to analysis in that data are analyzed by means of explicit rules called *criteria of selection* and these are formally established *before* the actual analysis of the data (see ETHNOGRAPHIC RESEARCH). The researcher seeks to establish criteria for selection that are sufficiently exhaustive that they can account for each variation in communication content and then apply these criteria such that others looking at the same messages would obtain comparable results. Although content analysis is often viewed as objective because of an emphasis on agreement between coders (often naive to research aims or hypotheses), the researcher still makes many interpretive judgments. This is especially true if codes move beyond the manifest content (the actual words or images that can be counted) to more latent or symbolic meanings conveyed by a message. Arguably, most categories of interest to market and consumer researchers are open to at least some interpretive ambiguity. For example, if a researcher wants to count instances of a theme, she must first establish what strings of words or images are constitutive

of that theme. Additionally, even with simple word or character counts researchers must be careful about what inferences they draw from descriptive statistics such as proportions and frequency distributions. For example, just because a buyer uses twice as many positive words in a product review as someone else, does not mean he is twice as happy with his purchase.

Content analysis is useful for researchers attempting to identify patterns, frequencies, or potential categories with respect to marketing and consumer phenomena. As used in marketing and consumer research, it is primarily a descriptive technique (see DESCRIPTIVE RESEARCH). Content analysis offers a number of benefits. It allows for an unobtrusive appraisal of communications; it can provide an empirical starting point for building theory about the nature and effect of specific communications; it can link message content to environmental variables, source characteristics and so on, and it can be effectively integrated with other types of qualitative and quantitative analyses.

The application of content analysis to marketing problems is likely to increase in the next decade. With an explosion of data in digital form, computer-assisted content analyses can now provide fine-grained semantic analysis of thousands of communications daily. One area that has received a lot of attention is *automatic sentiment analysis* which classifies documents, or chunks of text, into emotive categories such as positive or negative. There are numerous problems in marketing and consumer research that might be addressed by exploring the emotional content of large collections of open domain documents. For example, a company might use sentiment analysis to understand customer satisfaction by examining the range of affect in product reviews, what products are viewed most positively or negatively, how affect is linked to different features of a product and so on (see CUSTOMER-SATISFACTION RESEARCH). There are currently two basic approaches for identifying sentiment in text. Text classification models first hand label a set of documents for affect and then a system is trained on the vector features associated with the vector set. In the lexical approach, documents, phrases, or

2 content analysis

sentences are categorized as positive or negative on the basis of their match to a lexicon of sentiment-bearing terms. There are many challenges in doing this type of research but the burgeoning applications of these analytical tools suggests that this will be a high-growth application of content analysis in the future.

cross-tabulation

Mayukh Dass

When we are interested to determine how two or more categorical variables are linked in a study, cross-tabulation is one of the initial approaches to consider. In a cross-tabulation, we create a table similar to that of a FREQUENCY DISTRIBUTION to learn more about frequency distribution, but here, we merge the counts of different values of two or more variables. In other words, a cross-tabulation table is a way to present frequency distribution of two or more variables concurrently. The different values of the variables are considered categories, and they are cross-classified among each other (Malhotra, 2007). The cross-tabulation table is also known as a *contingency table*.

Although cross-tabulation tables can be generated for any number of variables, most useful tables for managerial purposes are formed with two or three variables. Table 1 illustrates an example of a two-variable cross-tabulation, which is also known as *bivariate cross-tabulation*. In this example, students from an undergraduate market research class were asked about their

liking toward pink lemonade. Their responses along with their gender identification are shown in Table 1. Since the two variables “likes pink lemonade” and “gender” are cross-classified, we can also compute the row and column percentages for each of the values. From the manager’s perspective, such a bivariate cross-tabulation provides information on (i) how the values of the two variables are related, (ii) which cross-classification is most selected by the respondents, and (iii) how these cross-classifications are different from each other. From the example shown in Table 1, we find that female respondents liked pink lemonade more than male respondents. More precisely, 85.71% (= 30/35) of the female respondents like a pink lemonade as compared to 68.57% of the male respondents.

When a bivariate cross-tabulation needs further clarification, a third variable, which is typically a categorization of one of the two variables, is considered. Continuing with the above example, let us include another variable, “gender age group,” into the cross-tabulation to further explain the relationship between male and female respondents. The resulting three-variable cross-tabulation table (Table 2) provides greater

Table 1 Cross-tabulation of liking pink lemonade by gender.

| <i>Question: Do you like pink lemonade?</i> | | <i>Gender</i> | | |
|---|-------|---------------|---------------|--------------|
| | | <i>Male</i> | <i>Female</i> | <i>Total</i> |
| Likes pink lemonade | Yes | 24 | 30 | 54 |
| | No | 11 | 5 | 16 |
| | Total | 35 | 35 | 70 |

Table 2 Cross-tabulation of liking pink lemonade by gender by age group.

| <i>Question: Do you like pink lemonade?</i> | | <i>Gender</i> | | | | <i>Total</i> |
|---|-------|---------------------------|---------------------------|---------------------------|---------------------------|--------------|
| | | <i>Male Age Group</i> | | <i>Female Age Group</i> | | |
| | | <i>Less than 21 years</i> | <i>More than 21 years</i> | <i>Less than 21 years</i> | <i>More than 21 years</i> | |
| Likes pink lemonade | Yes | 9 | 15 | 24 | 6 | 54 |
| | No | 4 | 7 | 3 | 2 | 16 |
| | Total | 19 | 16 | 27 | 8 | 70 |

2 cross-tabulation

details about the responses from two age-related subgroups of the variable “gender,” that is, “less than 21 yrs old” and “more than 21 yrs old.” Here, we find that pink lemonade is more popular among the female respondents who are less than 21 years than any other gender age groups. For further analysis on the relationship between the variables, NONPARAMETRIC TEST to learn more about nonparametric

tests such as a two-sample chi-square test are performed on the cross-tabulation data.

endogeneity

Neeraj Arora

Consider the regression model $y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \dots + \beta_k x_k + \varepsilon$ (see MULTIPLE REGRESSION). To consistently estimate model parameter β_1 it is required that $E(\varepsilon) = 0$ and $\text{Cov}(x_1, \varepsilon) = 0$. That is, the expected value of the error distribution is zero and it is uncorrelated with variable x_1 included in the model. However, if $\text{Cov}(x_1, \varepsilon) \neq 0$, then x_1 is considered endogenous. Failure to recognize endogeneity in a model leads to a biased estimate for β and therefore, requires careful attention. Endogeneity could be caused by three factors (Wooldridge, 2002, p. 51):

- *Omitted variables*: Factors unobserved by the researcher, often referred to as *demand shocks*, can affect both the demand and the marketing mix variables set by a manager. For example (Villas-Boas and Winer 1999) observe that it is plausible that an unobserved variable such as a manufacturer coupon drop could affect a retailer's price that is observed and included in the model. This induces a correlation between the error term and the included price variable thus causing an endogeneity bias.
- *Measurement error*: Measures in a survey have an associated measurement error. If this error is correlated in a systematic manner with the model error term we have an endogeneity problem (Gilbride, Yang, and Allenby, 2004).
- *Simultaneity*: The selected level of an independent variable is sometimes a function of the dependent variable. For example, Manchanda, Rossi, and Chintagunta (2004) note that promotion decisions (x) are often made simultaneously with y – high potential markets often get greater resources. The variable x therefore is not exogenously determined.

To address endogeneity, one possible solution is the use of *instrument variables* (IVs). This is accomplished by selecting a variable z_1 such that $\text{Cov}(z_1, \varepsilon) = 0$. That is, z_1 is exogenous to the system. Further z_1 and x_1 should

be partially correlated. For example, it is not uncommon to use lagged price terms or prices from “similar” geographic locations as possible IVs for price. Marketing applications of this approach include those by Hui (2004) and Nair, and by Chintagunta, and Dubé (2004). The basic idea is to use a two-stage approach by letting the IV z_1 predict the independent variable x_1 and using this predicted x_1 as a regressor in the demand equation. A problem here is that selecting an IV is more an art than a science. It requires instruments to be independent of an unobserved quantity (ε) a priori (Chandukala *et al.*, 2008). For most marketing problems, this does not appear to be an attractive solution. Another approach is to recognize heuristics used by managers in setting marketing mix decisions. That is, the demand and marketing variables could be modeled jointly by recognizing that the x decisions may be explicitly related to the expected demand or model parameters. A third solution is to assume an objective function of the decision maker (Yang, Chen, and Allenby, 2003) that helps a manager set the marketing mix variables. The objective function includes the model parameters that are a part of the demand equation thus leading to a system of equations that need to be jointly modeled.

In marketing, there is an increased recognition of the limitations of a reduced form model that ignores the underlying data-generating mechanism. In fact, an overwhelming majority of academic and practitioner marketing research suffers from the reduced form criticism. This has led to greater efforts to use structural models (Franses, 2005; Chintagunta *et al.*, 2007) that carefully account for endogeneity problems, among others. Shugan (2004) argues that two more considerations with regard to endogeneity deserve a special mention. First, there is no substitute for better data. When possible, most relevant independent variables should be included. Data fusion from disparate sources such as print, TV, and radio should be collectively used to explain demand. This is an attempt to hit the omitted variable problem head-on. Second, we as marketers should conduct more experiments (see CONCEPT OF CAUSALITY AND CONDITIONS FOR CAUSALITY). Such

experiments should try to assess response sensitivities in an attempt to address simultaneity concerns.

frequency distribution

Mayukh Dass

In a frequency distribution, each variable in the study is considered separately and a response count along with their percentages and cumulative percentages are computed for all different values of the categorical variable. This information is presented in a table, termed as *frequency table*, as shown in Table 1. A frequency table is not only effective to determine how the respondents have answered the questions but it is also useful in identifying cases of nonresponses or illegitimate responses in the dataset.

In order to illustrate the effectiveness of this analysis, let us consider a frequency table (Table 1) taken from a study performed on art collectors and dealers who frequently participate in online auctions of contemporary Indian art. In this study, the respondents were asked questions related to their browsing and bidding activities on a 7-point scale, with 1 = strongly disagree and 7 = strongly agree. Here, we consider one of those questions that ask the respondents about their browsing behavior during the auction. The frequency table suggests that 80.5% of the respondents, or 33 out of total 41, agreed (*somewhat agree*, *agree*, and *strongly agree*) that they browse the auction web pages and see who is bidding on what items while participating in an online auction. As you can see, the frequency

the responses in a study. Apart from analyzing the responses, the frequency table can be further used to perform NONPARAMETRIC TEST to learn more about nonparametric tests such as chi-square tests to determine the distribution of the variable reported.

As mentioned earlier, frequency distribution is also useful in detecting data errors and for finding ways to recode the data. For example, let us consider another frequency distribution taken from the same study performed on art collectors and dealers of contemporary Indian art. Here, we asked the respondents about the number of paintings they purchase each year. The frequency table as shown in Table 2 suggests three interesting characteristics about the dataset. First, it suggests that most people purchase at least 1 painting (mode = 1 with 18 respondents) each year. Second, it shows that there is an error in the dataset as the table shows one response with -4 paintings, which is not possible in the given context. When such errors are detected by the frequency distribution table, one should cross-check the responses with the actual study instrument to determine the origin of the error and recode the record accordingly. In this dataset, we found that it was a coding error and the response was 4 paintings and not -4. And third, the frequency table shows that the distribution becomes thin or the number of responses become small after 3 paintings. This indicates that we can group responses with

Table 1 Frequency distribution of online bidder behavior.

| <i>Question: I Typically browse through the Web pages and see who is bidding on what items</i> | <i>Frequency</i> | <i>Percentage</i> | <i>Cumulative Percentage</i> |
|--|------------------|-------------------|----------------------------------|
| Strongly disagree | 0 | 0 | 0 |
| Disagree | 1 | 2.4 | 2.4 |
| Somewhat disagree | 3 | 7.3 | 9.8 |
| Neither agree nor disagree | 4 | 9.8 | 19.5 |
| Somewhat agree | 8 | 19.5 | 39.0 |
| Agree | 15 | 36.6 | 75.6 |

multicollinearity

George R. Franke

Predictor variables in MULTIPLE REGRESSION that are highly correlated provide little independent explanatory ability. A scatterplot of one such variable versus another will show points falling close to a straight line, hence the term *multicollinearity* or simply *collinearity*. Because collinearity can have serious consequences for regression analyses, an extensive literature has developed on ways to detect and treat it in empirical research (Belsley, Kuh, and Welsch, 1980).

CONSEQUENCES AND INDICATORS OF HARMFUL COLLINEARITY

Perfect collinearity results when two or more predictors are completely redundant. In such cases, the model cannot be analyzed as specified. Much more common is near collinearity, where the shared variance between predictors increases the variance of the estimated regression coefficients. Potential consequences of this increased variance include estimated coefficients that (i) have theoretically implausible magnitudes or signs; (ii) vary substantially with small changes in the sample of observations or the set of predictors; and (iii) are individually nonsignificant even though they explain significant amounts of variance as a group. These results may not reduce the model's ability to predict values of the criterion variable. They are much more serious if the goal is to understand the relative importance of the predictor variables (*see* STEPWISE REGRESSION).

When regression outcomes are not consistent with expectations, researchers may (rightly or wrongly) interpret the results as consequences of collinearity. Several more direct tests are available:

1. Correlations of above 0.8 or 0.9 between predictor variables are often interpreted as excessively collinear. However, if one of two highly correlated predictors has only a small correlation with the criterion variable, it can "suppress" irrelevant variance in the other predictor. This pattern boosts the

variance explained by the model and reduces the standard errors of the regression coefficients. Similar results may occur if two predictors are positively correlated with the criterion but negatively correlated with each other (Mela and Kopalle, 2002). Therefore, researchers must examine the pattern and signs of the correlations and not just their magnitudes.

2. Sets of variables may be strongly related even though no two have a high pairwise correlation. Regressing each predictor x_i on all the other predictors gives the variance explained R_i^2 . The inverse of the unexplained variance for x_i , $(1 - R_i^2)^{-1}$, is known as the variance inflation factor (VIF). The VIF indicates the increase in the variance of the regression coefficient for x_i that is due to collinearity. A $VIF \geq 10$ is often thought to indicate harmful collinearity, though problems are possible with lower VIF values.
3. Condition indices (CI) are functions of eigenvalues of the scaled predictor variables. There are as many CIs as predictors, including the intercept, and each accounts for some proportion of the variance of each regression coefficient. Two or more predictors (including the intercept) that have large variance proportions, roughly 0.5 or greater, and that are associated with the same high condition index, larger than 20 or 30, may cause harmful collinearity.

REMEDIES FOR HARMFUL COLLINEARITY

Given an existing data set, researchers may combine or omit predictors, or constrain coefficients in theoretically justifiable ways (e.g., to be equal). The benefits and disadvantages of these approaches depend on how well they match reality. Ridge regression provides biased (conservative) estimates of the regression coefficients, in exchange for lower standard errors. Therefore, the analysis potentially offers more precise estimates that are less affected by small changes in the data. STRUCTURAL EQUATION MODELING may deal with collinearity by examining causal paths through a sequence of correlated variables, rather than testing each one controlling for the others, or by treating highly

2 multicollinearity

correlated variables as indicators of a common underlying construct.

Collinearity creates fewer problems when sample sizes are large, predictors have high variances relative to that of the criterion variable, and the model explains substantial variance in the criterion. Therefore, in many cases, appropriate model development and data collection procedures will be the best remedy for collinearity problems.

nonparametric test

Mayukh Dass

In marketing research, when a study contains variables that are measured in interval or ratio scales (see ITEMIZED RATING SCALES (LIKERT, SEMANTIC DIFFERENTIAL, AND STAPEL)), their means, variances, and standard deviations are meaningful and can easily be computed. For example, the mean of respondents' propensity to purchase a brand measured on a seven-point scale, with 1 = highly unlikely, 7 = highly likely, will provide insights to the sample's desire to purchase the product. Here, the data can be assumed to be drawn from a particular probability distribution and can be put through various parametric tests (see HYPOTHESIS TESTING RELATED TO DIFFERENCES – PARAMETRIC TESTS). There are also other instances where the scales used in a study are either nominal or ordinal in nature, and the measures have no clear numeric interpretation. For example, in case of gender classification of customers, "male" or "female" (nominal scale) are just used as a labeling scheme. Similarly, when customers provide a preference ranking of different brands of breakfast cereal, their responses (ordinal scale) include an order in which the brands are preferred, but not the difference in preference between them. In such situations, it is inappropriate to compute means, variances, and standard deviations of the variables as they do not provide any meaningful insights. Further, the assumption that the data are drawn from a particular distribution is not valid. In such cases, a different set of analyses called *nonparametric analyses* can only be used to analyze the data. The tests used for hypotheses testing are called *nonparametric tests*.

Nonparametric tests are performed when the variables measured are either in nominal or in ordinal scale. We can also use these tests on variables measured in interval or ratio scale if we cannot make any assumptions about the population probability distribution (Conover, 1999). Like parametric tests, nonparametric tests are categorized into one- and two-sample tests.

Two-sample tests are further classified into independent and paired-samples tests. While dealing with only one sample, we can perform five nonparametric tests: the Chi-square test, the Kolmogorov-Smirnov (K-S) test, the runs test, binomial test, and the sign test. The first four tests are different types of goodness-of-fit tests where the *Chi-square test* investigates whether the data came from a particular distribution, the *K-S test* compares the cumulative distribution functions for a variable with a specified distribution, the *runs test* examines the degree of randomness for dichotomous variables, and the *binomial test* investigates whether the observed responses for each category of a dichotomous variable follows a specified binomial distribution. Finally, the *sign test* is used to determine whether there are significant differences in preference between the two items of a dichotomous variable (Anderson, Sweeney and Williams, 2008).

In studies where two independent samples of nonmetric data are considered, four nonparametric tests are used: the *Chi-Square test*, the *Mann-Whitney U test*, the *median*, and the *K-S test*. In the given context, the *chi-square test* and the *K-S test* determine whether the two samples have the same probability distribution, the *Mann-Whitney U test* compares the difference in the location of two populations on the basis of the observations from the two samples and the *median test* examines whether the two populations from where the two samples are drawn have the same median. For paired samples, we can also perform four nonparametric tests including *sign test*, *Wilcoxon signed-rank test*, *McNemar test*, and *Chi-square test*. The *sign test* determines whether the paired differences of the paired sample is above or below a particular value, and the *Wilcoxon signed-rank test*, the *McNemar test*, and the *Chi-square test* examine the differences between the paired observations.

product moment correlation

George R. Franke

The Pearson product moment correlation coefficient is an index of the degree of linear relationship between two variables. It is named after British statistician Karl Pearson, who was stimulated by Sir Francis Galton's conceptual and empirical work on heredity to develop the mathematics and use of correlations. For two variables X and Y , the correlation r is computed as

$$r = \frac{\sum (X - \text{Mean}[X])(Y - \text{Mean}[Y])}{\sqrt{\sum (X - \text{Mean}[X])^2 \sum (Y - \text{Mean}[Y])^2}} \quad (1)$$

The numerator in the equation reflects the tendency of X and Y to be related. If high or low X values are associated with high or low Y values, the products of these terms will be higher (for positive correlations) or lower (for negative correlations) than if the X and Y values were associated at random. The sum of these products depends on the measurement scales of X and Y , such as monetary values recorded in dollars versus euro versus yen. Therefore, the covariation in the numerator is expressed relative to the individual variation of X and Y in the denominator to make r scale free and constrained to be less than or equal to 1 in absolute value.

A correlation coefficient is equivalent to a standardized regression coefficient in a model with a single predictor variable (see MULTIPLE REGRESSION). Therefore, r can be interpreted as the predicted standard deviation difference in Y for two observations that are different by one standard deviation in X . The strength of the relationship can be interpreted in terms of r^2 , the coefficient of determination, which gives the variance in one variable that is attributable to another variable. Rules of thumb for interpreting r are that population values of $r = 0.1, 0.3$, and 0.5 (positive or negative) can be viewed as small, medium, and large effects, respectively (Cohen, 1988). Estimated r values in samples from the population may be larger or smaller than the true value owing to sampling

error. The significance of r in a sample of n observations can be tested by comparing

$$t = \sqrt{\frac{r^2(n-2)}{(1-r^2)}} \quad (2)$$

with values from Student's t distribution with $n-2$ degrees of freedom. In planning a study, using a sample size of $n = 8/r^2$ gives an 80–90% chance of obtaining significant results at $\alpha = 0.05$ for a given population value of r (Dunlap and Myers, 1997; see also STATISTICAL APPROACHES TO DETERMINING SAMPLE SIZES).

FACTORS AFFECTING r

In general, r can range from -1 to $+1$. However, if the distributions of X and Y are not equal, the maximum absolute value of r is less than 1. If the relationship is nonlinear, calculating r for transformed variables, such as the square root or logarithm of X or Y , may improve interpretability. Range restrictions, such as limiting a sample to observations with above-average scores on X , can dramatically reduce estimates of r . Dichotomizing a continuous variable, such as converting raw scores to 0 for below the median and 1 for above the median, can also substantially constrain estimates of r . Correlating ratios (e.g., comparing per capita measures between countries or states) can make correlations appear artificially high. Difference scores (e.g., between one time period and another) and measurement errors tend to reduce correlations.

Combining samples may inflate or deflate estimated correlations. For example, if r is positive for men but negative for women, a sample of both sexes may yield an estimate of $r = 0$. Or r could be negative for both men and women separately, but positive for both sexes together. Outliers—atypical observations—may also have a variety of effects, including changes in the magnitude, significance, and sign of estimated r values.

Thus, while r is a useful summary of linear relationships between two variables, it may conceal more than it reveals depending on the nature of the data. When raw data are available for analysis, creating a scatter plot of the X and Y values is a useful tool to

2 product moment correlation

avoid misleading inferences from estimated correlation coefficients.

random coefficients modeling

Neeraj Arora

In marketing, it is important to recognize interpersonal differences in model parameters such as brand preference and price sensitivity. Unlike classical approaches in economics that view heterogeneity in model parameters as statistical nuisance, key marketing decisions such as product design and pricing mandate a careful understanding of interpersonal differences. In recent years, random coefficient modeling has significantly simplified our ability to characterize heterogeneity. A particularly useful aspect of random coefficient models that are discussed below is that each provides individual-level inference. This is critical for the field of marketing because not only are we concerned about the shape of the heterogeneity distribution but also how individual parameters vary with covariates such as demographics.

Consider the case of LOGIT MODEL, where the choice probability of alternative j for household i is $P_i(j) = \frac{e^{x_j'\beta_i}}{\sum_k e^{x_k'\beta_i}}$, where x_j is a vector of explanatory variables for alternative j and β_i is the vector of response coefficients for household i . To model unobserved heterogeneity, one can assume that individual response coefficients (β_i) come from an underlying distribution, sometimes referred to as the *mixing distribution* (see UNOBSERVED HETEROGENEITY; MODELS FOR CATEGORICAL DEPENDENT VARIABLES).

In the finite mixture approach (Kamakura and Russell, 1989), this distribution is discrete, that is, individuals are assumed to fall into M finite components (ϕ_m, β_m) such that $\sum_m \phi_m = 1$ and individuals belonging to component m have homogeneous preferences captured by the vector β_m . The number of components can be subjective and is often determined on the basis of a statistical fit criterion. An attractive aspect of this approach is that it nicely links to the theories of segmentation and has received considerable attention among academicians and practitioners in the 1990s (see LATENT CLASS AND FINITE MIXTURE MODELS). If the true underlying distribution of preference is continuous, the point mass approach of a finite mixture model

can be restrictive. A simple approach to characterize heterogeneity in such a case may be to use a multivariate normal distribution (Allenby and Lenk, 1994). Because of its simplicity and conceptual appeal, the multivariate normal distribution of heterogeneity has experienced considerable popularity in marketing.

An even more flexible approach may be to use a normal component mixture model (Allenby, Arora, and Ginter, 1998). That is, $\beta_i \sim \sum_m \phi_m \text{Normal}(\beta_m, D_m)$, where m indicates the number of components and ϕ_m is the mass of each component. The normal component mixture model is capable of representing a wide variety of distributions of heterogeneity. A skewed distribution, for example, can be obtained with a two-component model with the mass point ϕ_2 small relative to ϕ_1 , resulting in a thicker tail near the mean of the second component. As the diagonal elements of D_m approach zero, this model converges to a finite mixture model of heterogeneity.

In general, continuous distributions do a good job of characterizing the tails of heterogeneity distributions and therefore result in superior choice predictions (see Wedel *et al.*, 1999 for a review, and Andrews, Ainslie, and Currim, 2002). While the above discussion uses the multivariate normal as the kernel, other distributions such as gamma or beta may be better suited for applications, where the parameter space is restricted to be greater than zero or between 0 and 1, respectively. Another emerging approach to characterize heterogeneity uses the Dirichlet process mixture model prior (Ansari and Mela, 2003), which captures the uncertainty about the true functional form of the population distribution using a semiparametric approach.

To carry out estimation, finite mixture models use maximum likelihood methods. For continuous distributions of heterogeneity, Markov chain Monte Carlo (MCMC) estimation methods (Rossi, Allenby, and McCulloch, 2005) are commonly used. A particular advantage of MCMC methods is that they offer significant flexibility in specifying the functional form of the heterogeneity distribution. This is critical because accurate characterization of heterogeneity is an important consideration in order to develop models that are valid and actionable.

repeated measures ANOVA

Mayukh Dass

In marketing research, one of the sources of variability in the observed measures is the respondents themselves. The respondents come from different backgrounds and have unique individual characteristics, and thus can perceive a study differently. Since this sample level variability reduces the effectiveness of the study, it is very important to separate it from the treatment effects and the experimental errors. Unfortunately, these differences among subjects are uncontrolled and are treated as errors in a between-subject design. Therefore, we use a within-subject design where the respondents are exposed to more than one treatment condition and hence repeated measures are obtained. There are also other instances when such repeated measures are necessary. For example, in a longitudinal study, respondents are measured repeatedly in different time periods. Take the case of a brand loyalty study, where customers are asked about their level of loyalty on a particular brand, once every 6 months. In this case, the dependent variable, that is, "brand loyalty" is measured repeatedly twice a year from the same subject. Repeated measures also play a vital role when it is difficult to recruit respondents. In such cases, we expose the respondents to different conditions and take repeated measures instead of recruiting new subjects.

Traditional analysis of variance or ANOVA (see ANALYSIS OF VARIANCE AND COVARIANCE to learn more about ANOVA) is not adequate to analyze this type of data as it is unable to control the correlation among the repeated measures. Therefore, a different analysis called *repeated measures ANOVA* is used. Repeated measures ANOVA is considered as an extension of a paired-sample *t*-test to a case of more than two related samples

(Malhotra, 2007). To illustrate the underlying steps of the analysis, let us consider the case of single-factor repeated measures. Here, the total variation with $n(c-1)$ degrees of freedom is divided into a between-respondent variation and a within-respondent variation. The between-respondent variation with $(n-1)$ degrees of freedom captures the difference in means among the sample, and the within-respondent variation with $n(c-1)$ degrees of freedom captures the differences in the responses by the same respondent. The within-respondent variation is further divided into differences between the treatment means with $(c-1)$ degrees of freedom and the error variation with $(c-1)(n-1)$ degrees of freedom.

$$\begin{aligned} SS_{\text{total}} &= SS_{\text{between-respondent}} \\ &+ SS_{\text{within-respondent}} \\ SS_{\text{within-respondent}} &= SS_{\text{treatments}} + SS_{\text{error}} \end{aligned}$$

Using the within-respondent variation, we can now use the following *F*-test to test for equal means

$$F = \frac{SS_{\text{treatment}}/(c-1)}{SS_{\text{error}}/(n-1)(c-1)} = \frac{MS_{\text{treatment}}}{MS_{\text{error}}}$$

where $SS_{\text{treatment}}$ = sum of squares of the treatment, SS_{error} = sum of squares of the error, $MS_{\text{treatment}}$ = mean sum of squares of the treatment, and MS_{error} = mean sum of squares of the error.

stepwise regression

George R. Franke

Stepwise regression is both a general term and a specific method for choosing predictor variables from a larger pool of possible predictors in MULTIPLE REGRESSION. Eliminating redundant or irrelevant variables increases parsimony and may reduce the variance of estimated regression coefficients and predicted values (see MULTICOLLINEARITY). However, eliminating relevant variables biases the estimates for the remaining variables. Step-wise approaches generally use the same data for variable selection and model estimation, which can produce results that are not generalizable to other samples. Findings on the basis of stepwise approaches must therefore be interpreted with extreme caution.

METHODS FOR VARIABLE SELECTION

Many approaches have been developed for selecting predictors in multiple regression (Miller, 2002). Three of the most common are forward selection, backward elimination, and (in its narrow sense) stepwise regression. In forward selection, the best predictor is chosen from all available predictors, followed by the second-best predictor given the first predictor chosen, and so on. Backward elimination starts with the entire set of predictors and removes the worst predictor, followed by the second-worst predictor given the other predictors still in the model, and so on. Stepwise regression modifies forward selection to test the relevance of variables already in the model after each new predictor is added, and omits predictors that no longer meet criteria for inclusion. Statistical packages for regression generally allow users to specify criteria for variable selection, such as significance levels or F -values that must be met to enter or remove predictors. Other criteria include R^2 , the variance explained by the predictors; adjusted R^2 , which lowers R^2 as a function of the sample size and number of predictors; and Mallows's C_p , which is a measure of the model's prediction error that approximately equals $p + 1$ for correct models with p predictor variables.

These approaches may identify different sets of predictors as optimum according to the criteria specified. None of the sets will necessarily be the best of all possible combinations of predictors. Some regression packages can identify the best possible one-variable model, two-variable model, and so on, according to the chosen criteria. The number of models to evaluate equals 2^p , so with very large values of p , this approach may not be feasible. However, with p of at least 50 or 60, modern computers can perform the analysis in minutes.

PROBLEMS AND RECOMMENDATIONS

Because of random sampling error, the best set of predictors in one sample will often not be the best set in another sample or in the underlying population. Unless all p predictors are included in the analysis, significance tests and R^2 values may be far more liberal than their nominal values (McIntyre *et al.*, 1983). Some of the estimated coefficients are also likely to be substantially overstated relative to their population values.

For a given sample of observations, researchers using stepwise procedures may overlook how many other sets of predictors do almost as well as the selected set. Some of the alternatives are likely to perform better in other samples of observations. A simple check on the robustness of stepwise findings involves taking multiple random samples from the available data, and repeating the analysis on each subsample. Predictors that perform well in a majority of samples are good candidates for interpretation and application (Austin and Tu, 2004).

Stepwise regression procedures can be helpful tools for identifying important subsets of predictor variables. Researchers using them will generally get better results when they have large samples of observations and relatively small sets of potential predictors; when they consider multiple procedures and criteria for selecting predictors; when they cross-validate findings with new data or with random subsamples from the available data; and when they avoid self-deception in interpreting the findings.

logit model

Neeraj Arora

Consumer choice is arguably the most important variable in marketing. Examples include brand choice in a grocery store purchase, selection of a kitchen appliance at a retailer, or choosing a health club from the available alternatives. Choice is a discrete variable (taking a 0–1 value) and therefore does not lend itself to a linear regression model (*see* MULTIPLE REGRESSION; MODELS FOR CATEGORICAL DEPENDENT VARIABLES), where the dependent variable is continuous. On the basis of McFadden's (1974) random utility model of consumer choice, the utility for an alternative j in a choice set is

$$u_j = x'_j\beta + \varepsilon_j \quad (1)$$

where x_j is a vector denoting the features of alternative j , β is a parameter vector reflecting the person's preference structure, and the errors ε_j are assumed to have independent Gumbel distribution. For this model, the probability of choosing an alternative j can be shown as

$$P(j) = \frac{e^{x'_j\beta}}{\sum_k e^{x'_k\beta}} \quad (2)$$

In the brand-choice example, typical independent variables in a logit model include price, in-store promotions such as a special display and out-of-store promotions such as manufacturers coupon. The logit model is of great value because it allows a manager to understand the link between marketing actions and consumer behavior (Guadagni and Little, 1983). For example, the model can be used to conduct a "what if" analysis for a price change, an in-store display, or a coupon drop. Similar to the intercept term in a regression model, the logit model permits alternative or brand-specific dummies. The parameters corresponding to these dummies can be viewed as brand preference and provide a measure of relative preference of each brand. Some authors model state dependence in the logit model by including lagged terms (e.g., brand or flavor purchased in previous periods) as independent variables to capture interesting

behavioral constructs such as brand loyalty, habit persistence, and variety seeking (Erdem, 1996; Seetharaman, 2004).

Two popular application areas for the logit model in marketing include household-level panel data (Fader and Hardie, 1996) and choice-based conjoint analysis (Green and Srinivasan, 1990). The former are based on data collected by Information Resources, Inc. (IRI) and The Nielsen Company for most packaged goods available from grocery stores, mass merchandisers, and drug stores. The latter entails data collected in a choice experiment by carefully manipulating features of product alternatives across a series of choice tasks (*see* CONJOINT ANALYSIS). For a logit model, a popular measure of how well the model fits the data is the hit rate. This measure is based on the simple calculation of the percentage of times that the model prediction of the chosen alternative is the same as the actual choice.

While enormously popular, the logit model has limitations. We note two such limitations. First, the distribution assumption for the error term is fairly ad hoc and is guided by the convenience of obtaining a closed-form expression in Equation (2). Unfortunately, this choice of error distribution also results in an undesirable property called the *IIA* or *independence of irrelevant alternatives property*. From Equation 2 it is easy to see that

$$\frac{P(j)}{P(k)} = \frac{e^{x'_j\beta}}{e^{x'_k\beta}} \quad (3)$$

Notice that the ratio of choice probabilities for two alternatives is independent of other alternatives in the choice set. So, an implication of the logit model is that alternative similarity does not affect choice probability. This is clearly an undesirable property for contexts that involve similar alternatives – such as a consumer selecting between Coke, Pepsi, RC Cola, and Sprite – where they may be more likely to switch from Pepsi to Coke than to Sprite. A probit model with normal and correlated errors could be used to overcome this limitation. Another option is to use a nested logit model (Ben-Akiva and Lerman, 1985; Train, 2003). A second limitation is the implicit assumption that consumers use a compensatory evaluation process (Equation 1 in

2 logit model

selecting an alternative), that is, they trade-off all attributes against each other. It is certainly plausible that consumers, in certain contexts, may use a noncompensatory evaluation process. A conjunctive model of consumer choice (Gilbride and Allenby, 2006) could be used to overcome this limitation.

unobserved heterogeneity

Neeraj Arora

Heterogeneity, or interpersonal differences between individuals, could be categorized into two groups: observed and unobserved. Observables such as consumer demographics (age, gender, geographic location) could be included in a model to establish the link between model parameters and observed data. This is often referred to as *observed heterogeneity*. The remaining heterogeneity in model parameters, unaccounted for by measures available to the analyst, is called *unobserved heterogeneity*. In marketing, it is important to recognize and model unobserved heterogeneity when possible.

In general terms, a model could be viewed as $y = f(x, \beta, \varepsilon)$, where we attempt to explain the dependent variable y as a function of independent variables x and model parameters β (see MULTIPLE REGRESSION). Unexplained variation in y is captured via ε , the error term. For example, in a logit model, the dependent variable is choice and the errors are assumed to follow an independent Gumbel distribution (see LOGIT MODEL). For a given person i , the choice probability of choosing alternative j could then be written as $P_i(j) = \frac{e^{x_j \beta_i}}{\sum_k e^{x_k \beta_i}}$. In its simplest form, one could fit an aggregate model of consumer choice (Ben-Akiva and Lerman, 1985; Guadagni and Little, 1983) by assuming a response function that is homogeneous across the population of interest. The consumer choice in this model is explained entirely by the marketing mix elements included. Importantly, it is assumed that $\beta_i = \beta$ for all i .

A limitation of an aggregate model is that no attempt is made to assess how the response parameters vary across the population of interest. This highly restrictive assumption of constant model parameters across all units of analysis is undesirable for most marketing applications. For example, if the independent variables (x_j) in this model include price, in-store promotions (e.g., a special display), and out-of-store promotions (e.g., manufacturer coupons) then it is safe to assume that the corresponding model parameters (β) should be different for each person i . It is well known, for example, that consumers

exhibit differential sensitivity to price changes and promotions.

When testing theory, economists often attempt to characterize the “average” consumer. Observed heterogeneity caused by variables z_i is typically handled by expressing $\beta_i = z_i \gamma$ and estimating γ instead of β . However, unobserved heterogeneity is often treated as a nuisance parameter. In contrast, careful characterization of unobserved heterogeneity is at the heart of most marketing decisions. For example, we often attempt to segment the market on the basis of interpersonal differences in price sensitivity, product feature (e.g., low fat, high fuel efficiency) sensitivity, and brand preference. Indeed product-line length decisions are inextricably linked to accurate characterization of unobserved heterogeneity. From a statistical standpoint, it is important to carefully model unobserved heterogeneity because aggregate models suffer from biased parameters (Blattberg and Neslin, 1990, p. 181) and subsequent marketing actions on the basis of biased estimates are likely to be suboptimal.

Ability to accurately characterize unobserved heterogeneity requires multiple observations for each unit of analysis. This is certainly plausible for syndicated data available from Information Resources, Inc. (IRI) and The Nielsen Company for most packaged goods available via grocery stores, mass merchandisers, and drug stores. Unobserved heterogeneity among purchasing households or stores, typically explains significant variation in any type of a model. Another context is conjoint analysis (ratings and choice based), where the very purpose of the experiment is to uncover the heterogeneity in relative importance of product features across the population of interest (see MULTIPLE REGRESSION). Recent innovations in computing power and Bayesian simulation-based methods of model estimation (Train, 2003; Rossi, Allenby, and McCulloch, 2005) have significantly simplified our ability to estimate models with unobserved heterogeneity (see RANDOM COEFFICIENTS MODELING).

customer-satisfaction research

Vikas Mittal

INTRODUCTION

Customer-satisfaction research is widely undertaken by marketing-research departments worldwide. The logic for conducting customer-satisfaction research is undeniable. Customers are the biggest source of cash flow for a company. If a majority of a firm's customers are satisfied, then a variety of positive outcomes occur. Satisfied customers are likely to continue repurchasing a firm's offerings, purchase more from the firm, engage in more cross-buying, and have lower service and retention costs. Satisfied customers help a firm to lower the cost of customer acquisition through positive word of mouth and recommendations to friends and family. They also have lower price elasticity, that is, are less likely to defect when competitors offer lower prices. Finally, they are also more forgiving: when there is an occasional product or service failure; highly satisfied customers may attribute it to external causes and stay loyal to the firm. New research also shows that a strong customer-satisfaction reputation reinforces a firm's reputation in areas such as corporate-social responsibility and financial performance, leading to a virtuous cycle of positive performance. No wonder firms invest heavily in customer-satisfaction research to monitor and assess the satisfaction level of their customer base.

Customer-satisfaction studies in firms, typically, are conducted in the form of cross-sectional surveys. Results from these surveys can be aggregated over time as tracking studies. In addition to this research done by firms, a sizable amount of customer-satisfaction research has been conducted at the macro level as well. This macro-level research has provided marketing managers with a credible and robust view of the satisfaction-financial performance linkage and is described next.

CUSTOMER-SATISFACTION RESEARCH: STRATEGIC OVERVIEW

Macrolevel customer-satisfaction research that uses a firm as the unit of analysis is primarily

available through the American Customer-Satisfaction Index (ACSI) at the University of Michigan Business School. The ACSI was developed by the National Quality Research Center at the University of Michigan to obtain a customer-based measure of firms' ability to satisfy customers (Anderson, Fornell and Mazvancheryl, 2004). A representative sample of approximately 250 current customers from each firm is interviewed each year using computer-assisted telephone interviews. A different sample of customers is contacted each year. All respondents have purchased and used products or services from the firm in a defined period of time. For a given year, the database contains over 200 000 customer surveys. Twenty-five industries from the retail, finance/real estate/insurance, durable manufacturing, nondurable manufacturing, basic services, and transportation/communications/utilities sectors are included in the ACSI dataset. The following industries are represented in the sample (a subset of the firms in the sample is noted in parentheses): apparel (Liz Claiborne, Levi Strauss); athletic shoes (Nike, Reebok); automobiles (Chrysler, Honda); banks (Wells Fargo, Key Bank); brewing (Anheuser-Busch); department stores (Federated, May); discount stores (K-Mart, WalMart); fast food (McDonald's, Wendy's); food processing (Dole Foods, Heinz, Kellogg, Quaker Oats); hotels (Promus); household appliances (Maytag, Whirlpool); soft drinks (Coca-Cola, Pepsico); personal care (Dial, Colgate-Palmolive); personal computing (Compaq, Dell); pet foods (Ralston); service stations (Mobil, Texaco); supermarkets (Kroger, Safeway); tobacco (Phillip Morris); telecommunications-long distance (MCI, Sprint); telecommunications-local (BellSouth, US West).

In the ACSI measurement system, customer-satisfaction ratings are obtained from customers of each individual firm and used to create a customer-satisfaction index that can range from 0 to 100, with 100 as the highest level of satisfaction. A key advantage of this measure is the methodological consistency across all firms and over time. In other words, exactly the same survey instrument, interviewing methodology,

2 customer-satisfaction research

and statistical techniques are applied. An individual firm can thus benchmark its performance against competitors in the same industry as well as monitor performance relative to other industries.

Several academic studies have established a strong association between customer satisfaction and firm financial performance measured as long-term shareholder value, return on investment (ROI), return on assets (ROA), cash flow, risk, bondholder return, and so on. These studies also document that the strength of association can vary by many factors such as industry, firm efficiency, and diversification. One study examining the association between firm-level customer satisfaction and long-term shareholder value found a strong association in industries such as department stores, supermarkets, appliances, life insurance, consumer electronics, but relatively weak association in industries such as property insurance, food processing, personal computers, apparel, and automobile. Scholars have also shown that customer-satisfaction scores at the firm-level are best understood within the context of other factors such as the firm's corporate-social responsibility behavior as well as diversification strategy.

This macrolevel research using the ACSI is particularly important for marketing researchers as they can use it to establish the initial connection between a firm's satisfaction scores and financial performance. This is relatively easy to do, as firm-level satisfaction scores can be downloaded from the ACSI website. If needed, industry-level trends can also be monitored using the ACSI. Building on this initial evidence, marketing departments can make the case for their company to conduct customer-level research to measure and monitor satisfaction.

CONDUCTING CUSTOMER-SATISFACTION STUDIES FOR A FIRM

At the heart of every satisfaction research is a carefully designed satisfaction survey. Particular attention should be paid to the survey content and design, design of the sample, survey methodology, and the analysis plan.

Satisfaction survey design and content. Though the satisfaction survey for each firm must be adapted to its specific situation, a typical satisfaction survey consists of four parts. These are (i) measures of overall satisfaction, (ii) measures of behavioral intentions, (iii) attribute-performance perceptions, and (iv) background information.

Overall customer satisfaction. Professor Richard L. Oliver did pioneering work in defining satisfaction from the customer's perspective. Customer satisfaction is a summary judgment that has both an attitudinal and affective component, and which describes the cognitive and affective reaction of customers toward their consumption experience. In a typical customer-satisfaction survey, the construct is measured by asking customers to rate their overall experience with the company's product or service. Firms use a variety of overall satisfaction items such as

- a. Overall, how satisfied are you with ...' (1 = extremely dissatisfied, 5 = extremely satisfied).
- b. Please rate your agreement with the following item: "I am very satisfied with ..." (1 = strongly disagree, 10 = strongly agree).
- c. How would you rate your experience with ...' (1 = poor, 7 = excellent).

There are dozens if not scores of different overall satisfaction scales, each with its own advantages and disadvantages. Empirical research, however, shows that different scales tend to perform adequately and should be chosen on the basis of the context of the particular firm. More generally, a firm should pretest a few different scales to assess their suitability for its purpose. From a practical standpoint, it is important to ensure that the scale has face validity and finds acceptance within the firm especially the marketing department and frontline employees who would most likely use the results of the customer-satisfaction study.

Behavioral intentions. These include measures such as likelihood to repurchase, likelihood to recommend, and likelihood to complain. Similar to customer satisfaction,

behavioral intentions can be worded in many different ways:

- a. How likely are you to repurchase brand XXX in the next six months (1 = not at all likely, 10 = completely likely)?
- b. Would you be likely to repurchase . . . (1 = definitely not, 5 = most definitely)?
- c. Would you recommend this brand to your friends and family (1 = definitely will not recommend, 7 = will definitely recommend)?

Sometimes, firms also measure retrospective self-reports of behavior. These can provide useful insights as well. For instance, research has shown that overall satisfaction ratings predicted self-reported word-of-mouth activity among a national sample of customers. Similarly, researchers have also shown customer satisfaction to predict self-reported share of wallet (SOW).

Attribute-level perceptions. Typically, the survey measures customer evaluations on various attributes. For example, a customer-satisfaction survey for the automotive industry may measure performance on attributes such as “interior roominess,” “fit and finish,” “reliability,” and so forth. A banking survey may include attributes like “waiting-time in line,” “respect by employees,” and so forth. A satisfaction survey for health care may include “correct diagnosis,” “doctor doesn’t rush me,” and “doctor treats me with respect.” Performance ratings on each attribute can be obtained using a variety of scales:

- a. Rate the performance of each attribute as “excellent = 5, very good = 4, good = 3, fair = 2, poor = 1.”
- b. How did the product perform based on your expectations? Responses are obtained as: (above my expectations, met my expectations, below my expectations). This is a typical expectation disconfirmation scale, though, used by many firms to measure attribute performance.

An important aspect of developing the attribute list is to ensure that the list incorporates the customer’s point of view. For

this, marketing researchers should ensure the following:

- The items should not just use the manager’s judgment. Instead, qualitative research such as focus groups should be used to surface key attributes of the product and/or service from the customer’s point of view.
- The items generated should not overlap conceptually. For instance, a car dealership may measure “politeness” and “courteousness” of the service staff. However, if these two are highly correlated, it may pose problems in the multivariate analysis because of multicollinearity.
- The items should be worded using terms that are familiar to, and easily understood by the customers. Thus, technical jargon should be avoided in wording the attributes.

Customer background variables. In addition to demographics like gender, age, income and so forth, a satisfaction survey may also measure ownership of competitive brands (in an automotive study), or balance at other banks. These latter measures enable a firm to engage in competitive assessment. Typically, these background variables can be used to segment the customer base for subcell analysis.

Survey sample. A typical sample for a customer-satisfaction study includes customers who have purchased and/or used the firm’s offering in the past, during a prespecified period of time. Such an approach lets firms get a snapshot of their current customers. However, it is also useful to measure customer-satisfaction perceptions among past customers, that is, customers who are no longer with the firm. Similarly, measuring customer satisfaction among potential customers is also useful because they are the customers who typically use competitive offerings. Thus, in an ideal situation, the firm would conduct a satisfaction survey with the following samples:

- Current customers who are using the firm’s offering.
- Past customers who no longer use the firm’s offerings. They are also termed as “*lapsed customers*,” “*former customers*,” or “*defectors*.”

4 customer-satisfaction research

- Potential customers who currently use competitive offerings but not the focal firm's brand. In many cases, potential customers could have been past customers of the firm.
- Finally, for our services (e.g., banking and insurance) and products (e.g., automobile) is it possible for customers to simultaneously use multiple brands? In such cases, firms should measure overall satisfaction and behavioral intentions toward all the relevant brands.

Broadening the sample in this way is strategically useful in many ways. A comparison of customer-satisfaction scores and intentions between current and potential customers provides competitive benchmarking for overall satisfaction score, and attribute-performance scores. Comparing current and past customers can provide insights into why customers may have left the firm. Some studies have also found differences in customer satisfaction based on how long a current customer has been with a firm. Expectedly, customers who have been with a firm longer are more satisfied than customers who have been with the firm for shorter durations. Further, the relative importance of attributes varies on the basis of tenure. In the automotive industry, product performance is more important early on, but dealership importance becomes more important after three years of ownership.

Studies have also shown some differences in customer-satisfaction scores based on demographics, though the nature and direction varies by industry. Thus for many durable goods, females exhibit higher scores than males, older customers are more satisfied than younger customers, and higher income/education shows a negative association with customer-satisfaction scores. Thus in analyzing customer-satisfaction scores, it is useful to statistically control for these factors.

Survey methodology. A satisfaction survey can be conducted in many ways, with mail, telephone, and Internet being the most prominent methodologies (see SURVEY RESEARCH). Clearly, each methodology has its own advantages and disadvantages. Compared to a telephone survey, a mail survey is cheaper.

However, it is less versatile than a phone or Internet survey in that skip patterns and item randomization are not possible in a mail survey. However, compared to a phone survey, a mail survey affords the respondent privacy and reduces demand bias due to acquiescence. Some studies have found that satisfaction scores from telephone surveys tend to be higher than mail surveys because respondents are less likely to say negative things about the company to another person. A telephone survey, while being more expensive, is faster than a mail survey, and affords the interviewer opportunities to probe and follow up the responses provided. For instance, the interviewer can probe customers who indicate they are very dissatisfied. This flexibility is unavailable in a regular mail survey. Finally, Internet or web surveys are becoming popular as a relatively inexpensive way to reach a mass audience. Especially for firms having a robust database of email addresses, this can be an attractive survey methodology that combines the virtues of a mail survey with the speed of a telephone survey.

Overall, each methodology has its strengths and weaknesses. When cost is not a concern, a telephone methodology would be recommended. However, mail and online surveys by virtue of nonintrusiveness may provide more accurate data. In understanding these issues, especially cost, it is also important to consider the unintended positive benefits of such research. Marketing scholars have done a series of studies showing that customers filling out a satisfaction survey – irrespective of the rating they give – not only buy more from the firm later on, but are also more profitable. The basic logic is that being requested by the firm to be part of a customer-satisfaction survey sends a signal to the customers that the firm cares. This, in turn, prompts positive behavior among customers. In fact, calculations show that virtually in all cases customer-satisfaction studies pay for themselves from increased revenue and profitability.

Analysis of customer-satisfaction surveys. The analysis of a customer-satisfaction survey can take many forms ranging from basic univariate analysis to advanced multivariate analysis. We can look at it in increasing order of complexity.

Univariate descriptive (cross-sectional).

This is the most commonly used approach. Here either the average score or some variation of the “top box score” (e.g., top-2 or top-3 box) is used to describe the data (*see* PRODUCT MOMENT CORRELATION). Thus the average for top-2 box score is displayed as bar charts for overall satisfaction, attribute performance, and various behavioral intentions. Frequently, these are broken down by customer characteristics deemed relevant (e.g., by gender, age, brand ownership, number of years with the firm, and so forth).

Univariate descriptive (over time). If a firm conducts the customer-satisfaction survey over time (e.g., every year), the average scores or top box scores can be displayed over time to examine trends in the firms’ scores on customer satisfaction, behavioral intentions, and attribute performance. Most firms use the tracking studies extensively to monitor their customer base over time.

Bivariate analysis. To understand the association between overall customer satisfaction and intentions, some firms complete the correlation between the two (*see* PRODUCT MOMENT CORRELATION). In some cases, the association of attribute-performance ratings with overall customer satisfaction is calculated using bivariate correlation. This is used to rank order attributes such that the attribute with the highest correlation with overall satisfaction is deemed most important. Statistically, this approach is quite problematic as it does not account for the underlying correlation structure in attribute ratings. Multivariate analysis is required for addressing multicollinearity.

Multivariate analysis. This is used most often to ascertain attribute importance (*see* MULTIPLE REGRESSION; MULTICOLLINEARITY). With overall satisfaction as the dependent variable, and attribute-performance ratings as the independent variable, a multiple regression model can be estimated. The coefficient of each attribute variable denotes its relative importance. The idea is that the higher the relative impact of an attribute on customer satisfaction, the more important it is as a driver of customer satisfaction. Practically

speaking, such statistical models must account for the problem of multicollinearity since attribute-performance ratings obtained from the same survey tend to be highly correlated, sometimes owing to the halo effect.

Importance-performance analysis. This analysis uses the importance estimate from the multivariate regression, combined with the performance ratings on attributes (e.g., top-2 box score or average rating) to classify attributes into four groups:

- attributes that have high importance and on which the firm is performing high represent strengths of the firm;
- attributes that have high importance but on which the firm has low performance represent weaknesses that should be immediately addressed;
- attributes that have low importance but on which the firm has very high performance indicate that the firm may be overinvesting in that attribute. A strategy that may be adopted would be to increase the perceived importance of the attribute.
- attributes that have low importance and on which the firm has low performance, indicate that continuous monitoring is warranted lest either changes dramatically.

An importance-performance analysis results in a 2×2 map where the Y -axis shows the relative performance and X -axis shows the relative importance of each attribute. While different terms like “quadrant analysis,” “strategic attribute mapping,” “product-aspect maps” are used, the basic logic remains the same. Sometimes, on the same map it is useful to also plot the relative performance of “best-in-class” competitor for benchmarking purposes. Firms can use these importance-performance charts to develop concrete action plans for driving up customer satisfaction.

Smart firms take a return on quality (ROQ) approach to importance-performance analysis. Popularized by Professor Roland Rust and his colleagues, the ROQ approach suggests that rather than being an afterthought, the financial impact of all quality-related investments in customer satisfaction should be quantified.

6 customer-satisfaction research

They conducted a study at Chase Bank to show how investments in quality improvements, when measured, had a statistically significant impact on overall financial performance.

USING THE RESULTS OF A CUSTOMER-SATISFACTION STUDY

How do firms use the results of a customer-satisfaction study? A recent, in-depth study of over 120 managers from 35 businesses provides critical insights in this regard. Among others, the study arrived at the following conclusions:

- Over 90% of the firms used their customer-satisfaction study to examine current attribute level and overall satisfaction scores compared to past scores. However, less than 20% examined overall satisfaction and behavioral intentions, and only 3% related customer satisfaction to actual customer behaviors.
- With respect to analysis, 92% of the firms conducted univariate analysis like describing the mean and top-2 box scores. Only 38% conducted any bivariate analysis such as two-way cross tabulations or correlation analysis. Surprisingly, less than 1 in 10 (8%) did any multivariate analysis.
- Customer-satisfaction surveys were used in evaluating customer service, but few formal linkages existed to integrate customer-satisfaction scores with employee evaluation, compensation/rewards, and product/service development.
- Only 40% of the firms used their customer-satisfaction survey as a tool to learn about customers. A major impediment to wider usage was lack of formal structures to disseminate the results of the customer-satisfaction survey within the firm. The study found that 24% disseminated the results quarterly and 27% disseminated them on a monthly basis. In 86% of the studies the customer-satisfaction reports and dissemination efforts were targeted to senior management. In 62% of the firms, frontline employees were the target of dissemination efforts.
- Frequently, potential users viewed the customer-satisfaction information as being

provided “too late” for it to be usable. Even if provided on time, it was not seen as directly relevant to fixing customer-satisfaction issues from a customer’s perspective.

The study also identified several discouraging practices, including but not limited to the following:

- The focus was only on current customers to the exclusion of past or potential customers.
- More than half the firms did not conduct key-driver analysis to identify important attributes, and only two firms in the study linked overall satisfaction to postpurchase intentions.
- While customer-satisfaction data are disseminated to employees, the employees lack the training to use the data to identify root causes or fix customer-satisfaction problems. This makes them skeptical of customer-satisfaction studies.
- Satisfaction data is used mostly at a tactical, rather than strategic level.

Given these findings, firms interested in strengthening their customer-satisfaction research need to not only look at the actual research methodology (e.g., survey design, analysis plan, and so on) but also examine the organizational structures and processes by which customer-satisfaction research is disseminated and utilized within the firm. Clearly, the latter task requires intervention from and the support of top management.

EMERGING ISSUES IN CUSTOMER-SATISFACTION RESEARCH

Over time, and more recently, many issues have emerged in the conduct of customer-satisfaction research. Some important issues are described below.

Customer satisfaction and net promoter score.

Popularized by Reichheld as an alternative to measuring customer satisfaction, the Net Promoter score is based on a customer’s likelihood to recommend the firm’s offering to others. It is based on the difference between “promoters” (e.g., those giving a 4/5 on

a 5-point likelihood to recommend) and “detractors” (i.e., those giving 1/2). Many carefully conducted studies comparing the predictive ability of customer satisfaction and Net Promoter show the superiority of customer satisfaction in predicting key financial metrics. One large-scale study using the ACSI conclusively showed that customer-satisfaction scores predicted cash flow, long-term shareholder value, and other stock market metrics, while the Net Promoter score had zero predictive ability. Scholars have also highlighted the theoretical inadequacy and possible statistical problems in Reichheld’s original analysis. Given this robust evidence, the use of Net Promoter score, in lieu of customer satisfaction, should be discouraged. It seems that Net Promoter score, as a concept, is not only conceptually and empirically flawed, but also that its use discourages firms from focusing on more useful concepts such as customer satisfaction.

Behavioral consequences of customer satisfaction.

It is important to go beyond simple intentions that are concurrently measured in the same survey as customer satisfaction for two reasons. First, the halo effect can inflate the observed association between customer satisfaction and intentions. Secondly, intentions and behavior are not the same construct. Thus, imputing the behavioral consequences of customer satisfaction based on intentions may be misleading. The current thinking in customer-satisfaction research is that firms should collect actual behavioral metrics from internal records and link them to customer satisfaction. For instance, using actual behavioral data (and not just self-reports), studies have found a link between customer satisfaction and (i) repurchase of automotive brand, (ii) bank balance, and (iii) customer tenure at many firms. Recently, scholars have shown that customer satisfaction is not only linked to market share, but more importantly to the SOW, especially in financial services. More importantly, the functional form linking customer satisfaction to intentions (e.g., decreasing returns) can be very different than the functional form linking customer satisfaction to actual behavior (e.g., increasing returns). Hence, when available, one should use actual behavior and not intentions as the dependent variable.

The satisfaction-profit chain. In an attempt to apply customer-satisfaction research more comprehensively and strategically, the satisfaction-profit chain (SPC) is used as an underlying template. A typical satisfaction survey links attribute performance to overall satisfaction and overall satisfaction to behavioral intentions. The SPC links attribute-performance perceptions to operations inputs. Thus, “waiting-time in line” may be linked to the number of tellers per branch. Attribute performance is linked to overall satisfaction, which is linked to behavioral intentions. Downstream, behavioral intentions are linked to actual customer behaviors and, finally, financial metrics like sales and profitability. Such a comprehensive modeling approach is being increasingly used in financial services, hospitality, healthcare, and business-to-business services. For instance, useful statements like the following can be made: A \$2 million investment in teller training is linked to 0.25 unit change in “tellers are polite.” Increasing customer satisfaction by 0.5 units translates into \$3.8 in increased bank balance per customer and \$0.04 change in profit per customer. Using such information, the firm can understand the full impact of its customer-satisfaction investments. This is fully consistent with the “return on customer satisfaction” approach which argues that such spending is best viewed as a strategic investment and not an expense.

Customer satisfaction and service quality. Recognizing that service quality and customer satisfaction are conceptually different constructs is important. The initial debate about causal sequence has been resolved to a viewpoint that service quality is a key antecedent of customer satisfaction. Empirical studies also show both of them to be highly correlated with studies finding correlations in the range of 0.80–0.95. Thus while they should not be used interchangeably, there may not be a pressing need to separately measure them and expect different results from a practical point of view.

Customer satisfaction and employee satisfaction.

There is an increasing trend to try and link a firm’s employee-satisfaction scores to its customer-satisfaction scores. Despite the

widespread belief that employee satisfaction leads to firm profitability, studies have failed to find a direct link between the two. A recent study evaluated all the empirical evidence linking employee satisfaction to organizational financial performance. Except for two studies, all other studies found a zero correlation between employee satisfaction and financial performance measures like sales and profitability. Unfortunately, the belief that these two are related persists.

Instead, the study found that employee satisfaction is strongly related to customer satisfaction, and customer satisfaction robustly affects a firm's financial performance metrics. In other words, the effect of employee satisfaction on financial performance was fully mediated through customer satisfaction. This finding has profound implications for customer-satisfaction research. At the very least, it implies that both customer-satisfaction studies and employee-satisfaction studies should be analyzed together to fully understand the factors that drive a firm's profitability. In a study of Brazilian banks, the authors found human factors (e.g., satisfaction with tellers and bank managers) to be more consequential for profitability than technology factors (e.g., number of automatic teller machines at a bank branch). However, they also found that the cost of improving performance on human factors was 4 times as high as the cost of improving performance on technology factors. Clearly, when integrating employee satisfaction with customer satisfaction, and evaluating it as a causal factor, cost-related issues should also be considered.

Nonlinearities in satisfaction research. When estimating the relationships among constructs such as attribute performance, overall satisfaction, repurchase intentions, and repurchase behaviors, most marketing researchers assume their relationship to be linear. Recent research shows this may not be the case. Many of the relations are asymmetric, that is, a decrease from the midpoint has a stronger negative effect than the positive effect of a corresponding increase in attribute performance. For instance, a study of automotive customers found that a decrease in performance had a stronger impact on overall satisfaction than a corresponding increase in

performance on attributes such as brakes (0.24 versus 0.00), transmission (0.35 versus 0.04), power and pickup (0.21 versus 0.06), and quietness (0.23 versus 0.11). Similarly, for health care, there was a stronger impact on satisfaction when performance was negative than when it was positive on attributes such as thorough/attentive physician (0.66 versus 0.11), spends time with me (0.40 versus 0.17), gives referrals (0.77 versus 0.07), and convenient office hours (0.37 versus 0.07). Clearly, on many such attributes, firms should strive to eliminate the negative before they try to accentuate the positive.

Research has also shown that many of the relationships particularly between overall satisfaction and its consequences are nonlinear, with some relationships showing increasing returns and others showing decreasing returns. Thus, a study of automotive customers showed that the link between satisfaction and repurchase intentions showed decreasing returns, while the link between satisfaction and repurchase behavior showed increasing returns. Similar nonlinearities have been found in industries such as banking, insurance, utilities, and healthcare. These industry-specific patterns should be incorporated in the analysis plan for a customer-satisfaction study.

CAUTION IN USING CUSTOMER-SATISFACTION RESEARCH

Despite its many virtues, customer-satisfaction research should be used cautiously. Listed here are several issues about which firms should be careful:

- When ascertaining attribute importance, that is, the impact of an attribute's performance on overall satisfaction, many analysts use bivariate correlation analysis. This can be grossly misleading, and multiple regression analysis should be used whenever possible.
- Given budget constraints, firms typically survey their own customer base to measure satisfaction. By surveying a smaller sample of lost customers (i.e., customers no longer with the firm) and competitor customers, insights from satisfaction surveys can be substantially improved.

- Many customer-oriented firms use customer-satisfaction studies to set action priorities. For instance, realizing lower performance scores on “comfort of waiting area,” a small regional bank’s marketing team wanted to refurbish the waiting areas in all its branches. However, no consideration was given to the cost-benefit calculation. In other words, customer-satisfaction surveys do not take into account the investments needed to implement the findings. For this, an ROQ or a return on satisfaction (ROS) is recommended.
- The above is consistent with the SPC that integrates customer satisfaction with both operations and finance within a firm. In doing so, attention should be paid to the profit implications (not just revenue enhancements) that result from investments aimed at improving overall satisfaction.
- Some researchers use the term *loyalty* to refer to intention items, especially intent to recommend. However, careful studies of the concept of loyalty show that loyalty is a multidimensional term with no agreed-upon way to conceptualize and measure it. For instance, some scholars differentiate behavioral (actual behavior) and attitudinal loyalty (based on intentions and attitudes). Given this disagreement, we suggest that marketing studies refrain from using the term *loyalty*. Rather specific terminology such as “behavioral intentions” or “repurchase intentions”, or “actual repurchase behavior” which is clear, specific and usable should be encouraged. In many cases, it is not known how repurchase intentions correlate with actual behavior. A large-scale study showed virtually no correlation between satisfaction and actual repurchase *behavior* for car buyers, even though satisfaction and repurchase *intent* were highly correlated.

CONCLUDING COMMENTS

Customer-satisfaction research has matured in its own right among market-oriented firms. As evidence mounts for the strong association between customer satisfaction and firm financial performance, firms need to move from using customer-satisfaction research as a descriptive tactic, to a strategic tool. In this article, we have described how a basic customer-satisfaction study is designed and conducted. More importantly, we have provided state-of-the art insights into its usage among firms incorporating the latest developments in academic research. We hope that this will help firms to not only evaluate their current practices, but also improve them in the near future.

consumer materialism

Marsha L. Richins

Consumer materialism refers to the importance that a consumer places on the acquisition and possession of material objects. In the consumer-behavior literature, materialism is usually considered to be a personal value, meaning that it affects the priorities in people's lives and the choices they make. Materialists believe that acquisition of material goods is a desirable and effective way to achieve important life goals. Thus, a materialist is more likely than others to see acquisition as a way to attain happiness, develop relationships with others, achieve status and a sense of self worth, and reach other important life goals. Richins and Dawson (1992) identified three elements that constitute materialism: the belief that acquisition is necessary for happiness, the tendency to judge the success of one's self and others by their possessions, and the centrality of acquisition and possessions in one's life. Because materialism is a value orientation and not a behavior, it is independent of financial status and is readily observed in both developed and developing economies. Materialism is most commonly measured by the material values scale (Richins, 2004).

Materialism should not be confused with conspicuous consumption, which is the ownership and display of status objects to enhance one's relative standing and inspire envy. While some materialists engage in conspicuous consumption, it is possible to have materialistic values without engaging in this particular behavior, particularly if status is not an important life goal for a consumer.

Although the formulation of materialism described above is the dominant one in consumer behavior, there are some alternative conceptualizations that should be recognized. Kasser (2002), a psychologist, has equated materialism with the pursuit of wealth, attractiveness, and social recognition and has looked especially at the negative effects of these goal pursuits on well-being. Inglehart (2008), a political scientist, has conducted extensive cross-national research over several decades to investigate the relative emphasis members of a society place on *material values* (defined as the importance one places on

economic and physical security) and *postmaterial values* (the priority assigned to such things as free speech and a greater say in government decisions). A third approach (Belk, 1985) views materialism as a combination of the personality traits of envy, nongenerosity, and possessiveness.

Materialism has important implications for society as a driver of personal consumption, and thus of economic growth. It also has personal implications because of its negative association with well-being (Christopher, Saliba, and Deadmarsh, 2009), strength of personal relationships, and altruistic behavior. Because of materialism's importance, much has been written about its potential causes. Commonly, high materialism levels have been attributed to insufficiently bridled capitalism coupled with a consumer society that is endorsed and facilitated by marketing firms, assisted by mass media. A lack of spirituality is also often alluded to. The preponderance of writings on the causes of materialism is speculative in content, and in any event the construct itself and the systems in which it is embedded are too complex to assign a single causal variable. However, some empirical research has provided insight by examining potential influences on individuals' materialism levels, including media exposure (Shrum, Burroughs, and Rindfleisch, 2005), early family environment (Flouri, 2004), and peer influences (Roberts, Manolis, and Tanner, 2009). The developmental progression of materialistic tendencies in children has also been investigated (Chaplin and John, 2007).

Materialism is associated with many variables of interest to marketers, including a preference for status goods and unique products, the centrality of visual aesthetics when making a product choice, willingness to purchase counterfeit products, impulse buying, and other decision variables. It is also associated with a greater willingness to go into debt to purchase discretionary goods, lower levels of frugality, compulsive spending, and with perceived financial distress and conflict between spouses.

consumer memory processes

Kathryn R. Mercurio and Mark R. Forehand

Consumer memory involves the encoding, storage, and retrieval of information related to products and services. The strongest consumer brands are those that have high brand awareness, whereby consumers easily recognize the brand (aided awareness) and can also recall the brand in the absence of cues (unaided awareness). Following associative network models of memory (Anderson and Bower, 1973), consumer memory is generally described as a massive network of interconnected ideas and concepts. The probability that any particular piece of information will be retrieved is dependent on the strength of association between the information and other connected concepts that are activated in the environment. When numerous pieces of information are integrated into a given associative network, the probability of successful recall of any particular piece of information may drop. For example, memory performance often lessens in the presence of competing information from competitive advertising (Keller, 1991) or from contextual interference (Kumar and Krishnan, 2004).

Consumer memory performance is critically influenced by the depth with which new information is encoded and the context in which the encoding takes place. For example, brands that are encoded in conjunction with parent categories and are considered more prototypical members of a category are usually easier to recall than are less representative brands (Mao and Krishnan, 2006). Brand concept maps have shown that the core brand associations that define a brand's image are connected not only to brand but also to secondary associations outside the brand (John *et al.*, 2006). These secondary associations provide an initial indication of the concepts that are likely to trigger memories for the brand in the external environment. There are also a number of marketing-controlled factors at the time of encoding that influence memory performance including message source (Kirmani and Shiv, 1998), persuasion (Drolet and Aaker, 2002), order effects (Cunha, Janiszewski, and Laran, 2008), virtual product experience

(Schlosser, 2006), sponsorship (Cornwell *et al.*, 2006), mode of encoding – visually, verbally, and so on (Vanhuele, Laurent, and Drèze, 2006), and repetition (Appleton-Knapp, Bjork, and Wickens, 2005).

The states a consumer is in during encoding and retrieval can also significantly influence the consumer's ability to retrieve learned information. Within an associative network, activated states can serve as central units or nodes in a semantic network and a reoccurrence of a state can, therefore, trigger improved recall of information associated with that state (Cowley, 2007). Two accepted models of state-based memory are state dependency and state congruency. State-dependent learning models suggest that memory performance improves when information learned under a particular activated state is retrieved while that state is again activated, regardless of whether the learned information is related to the state. In contrast, state congruent models propose that memory performance is driven by a match between an individual's state at retrieval and the a priori association of the learned content with the activated state (Fiedler, 2000). In advertising contexts that feature content ambiguously associated with a state, memory performance is only apparent when the same state is active at encoding and retrieval and the content is moderately related to the state (Mercurio and Forehand, 2009).

One way of improving memory performance in consumer contexts is to provide retrieval cues that activate critical information nodes that can in turn facilitate retrieval of closely associated information. Although these cues generally improve memory performance, they can also hinder long-term memory if the consumer becomes dependent on the cue for retrieval and does not reinforce the required retrieval pathways (Forehand and Keller, 1996).

Consumer memory is a dynamic and complex process and given the role of memory in almost all aspects of consumer behavior it is important to understand the marketing factors that facilitate or hinder memory performance. Memory performance depends on the ability to encode information into long-term memory, retain the information over time, and retrieve previously stored memory. As shown by the associative

2 consumer memory processes

network model of memory, factors present at encoding and retrieval can influence the strength of association between brands and new information and thereby significantly influence subsequent recall and recognition of consumer information.

online consumption

David Mazursky and Gideon Vinitzky

In view of its fast growth, little doubt remains about the central role that online consumption plays in practically every aspect of our marketing world. Much of the research interest in recent years has focused on whether the key consumer decision-making rules that we acquired over decades of research can be easily applied in the online consumption context, or alternatively, whether it involves unique characteristics which challenge our accumulated knowledge and predictions about how consumers behave. The emerging literature indicates that the on-line shopping process possesses several unique characteristics that distinguish it from other forms of transactions.

The study of on-line shopping focuses mainly on the effects of technological aspects of the Internet on consumers' experience, motivation to engage in the process, the unique process dynamics, and postconsumption behavior. The literature developed so far mentions two technological features of the Internet as affecting the way people make their purchases and the outcome of consumption: interactivity and vividness (Steuer, 1992). Although the literature offers different definitions of the interactivity concept (Rafaeli, 1990; Steuer, 1992) and different dimensions based on various theoretical frameworks, it is agreed that most web sites offer dimensions that enable consumers to hold instant-response dialogues with the electronic interface and salesperson, simulating a regular conversation between human beings. The second characteristic of the technological environment is vividness, defined as the clarity of information received by consumers in the virtual world (Steuer, 1992).

Researchers suggest that interactivity and vividness promote the experience of telepresence, defined as consumers' feeling when located within the Internet environment (Steuer, 1992). Telepresence enables consumers to enjoy the actual process of navigating the site and is characterized by intrinsic motivation. Hoffman and Novak (1996) suggest that the interaction between the consumer and the purchase interface has an effect beyond that of the information in the

shop, thus promoting the experience of flow, that is, the complete engagement with and immersion in an activity (Hoffman and Novak, 2009). The research states that the flow experience is more a characteristic of consumers in purchase tasks than of computer users on surfing tasks who have no purchase intentions and that the flow experience promotes exploratory, curiosity, and discovery behavior (control and perceived behavioral control, and learning).

What motivates consumers to engage in on-line shopping? From the financial aspect, buying on-line enables consumers to visit a large number of shops, increases the choice range of various products, increases competitiveness and gains from reduced prices (Bakos, 1997; Lynch and Ariely, 2000). From the cognitive aspect, consumers expect to benefit from the reduced cost of cognitive search (Lurie, 2004; Häubl and Trifts, 2000; Alba *et al.*, 1997), affecting also their sensitivity to price and quality (Lynch and Ariely, 2000). From the hedonic perspective, researchers suggest that on-line transactions provide consumers with types of pleasure that are similar to traditional transactions (Menon and Kahn, 2002) as well as other sources of enjoyment, for example, convenience and entertainment, that are uniquely associated with on-line purchasing (Childers *et al.*, 2001).

One of the most significant barriers to consumer entry when purchasing on-line is the concern of trust. Trust is a psychological state expressing reliance on another person or organization to do that what is required. Researchers state that trust is a multidimensional psychological concept that includes cognition, affect, and behavior (Johnson and Grayson, 2005). More concretely, factors affecting trust include site features (Shankar and Sultan, 2002), familiarity with the company and its reputation (Yoon, 2002), information security features (Belanger, Hiller, and Smith, 2002), ease of use, and expertise (Fogg *et al.*, 2001). At the same time, trust-motivating factors are distinctively affected by various product categories and interpersonal differences (Bart *et al.*, 2005).

Research on the dynamics of the on-line shopping process suggests that consumers demonstrate various search patterns stemming from the features of the interface (Mazursky and Vinitzky, 2005). Three-dimensional purchase

interfaces were found to promote a structured search process, which is more continuous and more compatible with physical shopping, while two-dimensional purchase interfaces were found to promote less structured search, which is quicker yet different from the search pattern characteristic of buying in a traditional shop.

On the basis of the preference construction approach (Bettman, Luce, and Payne, 1998), researchers suggest that consumer preferences change during the purchase process in line with various aspects of the purchase environment. Häubl and Trifts (2000) propose that the default values that appear in search agents affect the features examined in the purchase process. Mandel and Johnson (2002) found that the background color of a web site can serve as priming the criteria involved in product selection and that it affects the weight given to these criteria in the process of product choice.

The postconsumption factors consist of satisfaction, loyalty, and word-of-mouth communication. Studies offer various models for examining consumer satisfaction upon purchasing on-line. Szymanski and Hise (2000) suggest that the surfer's convenience, the products offered, site design, and financial safety issues, have an effect on satisfaction. Cheung and Lee (2005) focused on the quality of the various components containing the information displayed in the shop and how the system functions. Turban *et al.* (2008) expanded this model and added the component of quality of service provided on site. Surfer satisfaction, in turn, was found to impinge on a variety of shopping related aspects, including word-of-mouth (Parish, Holloway, and Wang, 2005; Chevalier and Mayzlin, 2006), trust (Bart *et al.*, 2005), and loyalty (Bolton, Kannan, and Bramlett, 2000; Floh and Treiblmaier, 2006).

The ease of access to a variety of alternative shops offering the same services (Lynch and Ariely, 2000) contributes positively to consumer loyalty. Keaveney and Parthasarathy (2001) suggest that previous consumer behavior patterns on the site (e.g., use of services), attitudes, involvement, and demographic variables, distinguish between consumers' loyalty status. Other factors found to promote loyalty are the quality of services on the site (Chen and

Hitt, 2002), consumer commitment (Pavlou and Gefen, 2004), and trust (Park and Kim, 2006).

However, experiences in on-line shopping may not always be positive. Presumably because of the relative ease to express negative feedback (in comparison with other forms of transaction), such activity is highly prevalent and has intrigued researchers' interest. The nonpositive pattern of postshopping behavior may involve revenge, negative rumor, and negative word of mouth. For example, writing negative on-line reviews may even lead to harming of sales (e.g., Chevalier and Mayzlin, 2006).

Finally, despite the noticeable progress in the study of on-line shopping behavior, its unique infrastructure represents an important research area both for studying on-line shopping, as well as for serving as a proxy for learning the way consumers form decisions in shopping behavior, in general. This infrastructure involves presenting information, prompting a decision, and echoing postconsumption reactions, all in vivo, and in a relatively condensed time framework, enabling tracking and analyzing the process. This is quite a unique setting compared with other forms of transactions such as in physical stores, where tracking this process generally involves tools that are largely artificial and inaccurate. In addition, the growing direct linking possibilities from the shopping activity to other network systems such as social networks, available in on-line shopping formats, further increase their research potential. The outlook is indeed promising, although possible barriers such as intercultural and language issues need to be carefully considered in planning future research.
